## ABSTRACT

Mantovani, Eder Eduardo; M.S.; Department of Plant Sciences; College of Agriculture, Food Systems, and Natural Resources; North Dakota State University; August 2011. Wheat Traits Variations, Associations, and Potential Improvement from Crosses of Elite x Non-adapted Germplasm. Major Professor: Dr. Mohamed Mergoum.

Wheat improvement most often has been accompanied by a narrowing germplasm base, as newer cultivars have been derived from intercrosses between elite germplasm. However, there is a concern that narrow germplasm may restrict breeding improvement for important traits such as resistances to new biotic and abiotic stresses. In addition to germplasm base, the wheat kernel is a major component of wheat grain yield and an important factor for milling characteristics. Focusing on wheat kernel characteristics might be a key element to improve wheat genotypes for agronomic and quality traits. With the intention to broaden the wheat germplasm, and to explore the associations between kernel traits and agronomic as well as quality traits, a two-year study was initiated in 2009 to examine the influence of the kernel traits on the agronomic and quality attributes of a 160 Recombinant Inbred Lines (RIL) population developed from an adapted (ND 705) and a non-adapted genotype (PI 414566). The experiment was conducted at Prosper and Carrington, North Dakota, during 2009 and 2010. The RIL population had a better performance at Carrington than Prosper due to favorable climatic conditions at this location, in 2009 and 2010. The results in this study showed that kernel traits had a high correlation among them and they exhibited continuous variations suggesting a polygenic inheritance. Grain yield, kernel volume weight (KVV), and flour extraction were highly correlated with kernel width, length/width ratio, weight, and area. Eight RIL yielded better than the adapted parent ND 705 and two of the RIL along with three checks were

significantly superior for grain yield compared with the other genotypes across all environments. Although the non-adapted parent has a facultative grown habit, several RIL required fewer days to flower compared to the adapted parent. Two RIL had better flour extraction compared to the other genotypes included in this study. These results indicated that kernel traits can play a significant role in improving agronomic and quality traits. Higher values for grain yield, K<sub>VW</sub>, and flour extraction were significantly associated with spheroid or round shape (short and plump), large, and heavy kernels. The high agronomic and quality attributes showed by some RIL demonstrated that the use of a non-adapted parent can broaden the genetic variability while increasing the genetic gain for certain traits. Also, breeders should pay attention to kernel size and shape during the parental selection for the development of populations with improved agronomic and quality traits.

## ACKNOWLEDGEMENTS

I wish to express my gratitude to many people who have directly or indirectly helped and supported me to complete my Master's degree. I am much indebted to my major advisor, Dr. Mohamed Mergoum, for providing me the great opportunity to pursue my Master's degree. I am very thankful for his guidance, valuable advice, and patience.

I gratefully acknowledge my committee members: Dr. Senay Simsek, Dr. Shahryar Kianian, and Dr. Steven Xu for their assistance and suggestions. Special thanks to Dr. Douglas Doehlert for his guidance on the kernel photographs, Dr. James Hammond for his suggestions during the statistical analyses, and Dr. Burton Johnson, Dr. Elias Elias, and Dr. Edward Deckard for their friendship and kindly granting me their time.

I would like to thank all my colleagues from the Hard Red Spring Wheat Program: Jesse, Matt, Daniel, Adam, Jeremiah, Morgan, Vibin, and Ahmed who assisted, helped, and made my days at work enjoyable.

I enthusiastically thank my family members: my parents, brothers, sisters, brothers and sisters-in-law, my nephews and nieces, and my fiancé, Monalisa for their love, care, encouragement, and support during my study.

I would like to express my gratitude to Dr. Glauco Miranda and Dr. Leandro Vagno for being my mentors in plant breeding and also to my friend, Fernando Eckert, for introducing and helping me with the application process at NDSU. Also, special thanks to my friends: Andre, Dante, Michael Miller, Roberto, Paul, Morgan, Renata, Jocleita, Francisco, Angela, Juan, Wesam, Ana, Magan, and Ronald for their support and the funny moments we shared.

**“Happiness is not a destination but a state of mind”**

## PREFACE

This thesis consists of two papers that will be submitted for publication in the appropriate scientific journals. The 'General Introduction' and 'Literature Review' provide a general review of the importance of this study, some previous research, and how the two papers are related to the main issues: wheat agronomic and quality trait variations in a population originated from a cross between an adapted x non-adapted genotype and the potential uses of kernel characteristics in breeding programs in order to develop new cultivars with higher grain yield and quality attributes. Subsequently each paper includes an abstract, introduction, material and methods, results and discussion, conclusion, references section, and appendix. The references for the 'General Introduction' and 'Literature Review' are cited in the 'General References' section.

## GENERAL INTRODUCTION

Wheat (*Triticum aestivum* L.) is one of the most important crops worldwide. In 2010, wheat harvest reached 222.2 million ha with a total production of 645.4 million tons. The average yield was 2.9 tons per ha. The USA represented 9.3 % of world wheat production with 60 million tons. The USA is consistently the world's biggest wheat exporter (28.2 % of the world exports) with 59 % of its production exported. Wheat ranks third among USA field crops planted acreage, behind corn and soybeans. (USDA-ERS, 2011).

Wheat in the USA entered the 21<sup>st</sup> century dealing with many challenges, despite a strong domestic market for wheat products. This is due to at least two reasons. First, wheat returns are falling compared to other crops, stemming in large part from foreign competition. Second, the government programs provide more support to alternative crops. Consequently, wheat harvested acreage has decreased nearly 12 million ha (35 %) compared to its highest acreages reached in 1981, and USA wheat export share percentage has also significantly declined in the past two decades (USDA-ERS, 2011).

Wheat, along with rice, is the main source of energy for humans. The world population keeps increasing, the production of wheat should follow the same pattern. Wheat production can be increased by expanding planted areas, improving the agronomic techniques, and/or developing improved varieties with higher yield potential. Expanding planted acreage is a limiting factor in many regions, and there are many environmental factors affecting crops, such as climatic conditions. Therefore, the development of new adapted cultivars coupled with improved agronomic practices remains the main factor to increase yield (Briggle and Curtis, 1987).

The wheat consumers are also becoming more exigent for wheat quality. Consequently, scientists are expanding more effort to improve wheat quality characteristics along with grain yield. Today, several traits such as grain protein content and kernel volume weight are being used routinely as markers for indirect selection for quality.

Wheat improvement has been in most cases accompanied by a narrowing germplasm base, as newer cultivars have been derived from intercrosses between elite germplasm. Therefore, wheat breeding programs are continuously improving and releasing varieties with higher agronomic and quality attributes with the use of narrow germplasm base. However, there is a concern that the narrow germplasm may restrict breeding flexibility and slow response to new challenges such as pests, pathogens, and agronomic practices in the future. Also, the tendency of the continuous use of the same germplasm base will at a certain point of time result in an even more restrict germplasm base. Due to these challenges, Breeders are constantly faced with broadening the genetic diversity using elite x non-adapted crosses.

Wheat kernel is the main component of wheat grain yield and quality. In addition, traits such as spikes per unit area, kernels per spike, and kernel weight are major contributing components in determining yield and quality of wheat. Many recent studies (Campbell et al., 1999; Breseghello and Sorrells, 2007; Sun et al., 2009) indicated that wheat kernel characteristics are important quality factors, particularly for milling characteristics. The focus on wheat kernel characteristics in the selection process might be a key element for the wheat quality improvement, therefore, increasing the possibility of achieving higher levels of success in the breeding programs.

The development of high performance cultivars for North Dakota with improved grain yield and milling attributes will raise the value of wheat, which will contribute to the increase of wheat growers and industry incomes. Similarly, high quality of wheat will allow the USA growers to be competitive in the international wheat export market.

## **OBJECTIVES**

The objectives of this study were:

- Explore the potential improvement of wheat agronomic and quality traits from crosses involving elite/adapted and introduced/non-adapted germplasm in wheat breeding programs.
- Study the agronomic and quality trait variations and their correlations in a Recombinant Inbred Lines (RIL) population developed from an elite x non-adapted parental cross.
- Study the kernel characteristics variations using a RIL population derived from an elite x non-adapted parents.
- Determine the associations between kernel characteristics and major agronomic and quality traits, and explore their potential uses in breeding programs in order to improve these traits.

## LITERATURE REVIEW

### **Broadening the germplasm base with the use of exotic lines**

Cereal crop species have been the focus of numerous genetic studies and crop improvement efforts due to the global agronomic importance of these species. The lack of genetic diversity, the problems of genetic vulnerability, and selection plateaus has been recognized (Gouesnard et al., 1996). The utilization of exotic germplasm is difficult due to its non-adaptability. However, it has been the most frequently identified procedure to broaden the germplasm base (Holley and Goodman, 1988). There are several reports on the transfer of genes from non-adapted wild relatives into cultivated hexaploid wheat (Miedaner et al., 2006; Nelson and Goodman, 2008); however this approach has not been widely used in wheat breeding programs which in most of the cases use crosses between elite x elite lines to release new cultivars. The reason for this is that favorable attributes are often linked to undesirable traits in non-adapted wild relatives and it is difficult to separate them. These linked groups are called linkage drag (Stalker 1980; Patterson et al. 1991).

A complete integration of exotic and elite chromosomes is required to avoid the loss of useful linked factors. Several generations of random mating, with or without mild selection, are recommended before the application of more rigorous selection (Eagles and Lothrop, 1994). The optimal proportion between exotic and elite germplasm to form the base population is also an important theme. This proportion is influenced by the divergence between the parents, the level of dominance of the considerable traits, the use of back-crosses to the elite material, and the short- and long-term goals. The exotic genes from the non-adapted parent should broaden the germplasm base, improve the considerable traits,

and be incorporated in the new released varieties. However, these goals must be achieved without negatively affecting the desirable traits already presented in the population.

Currently, many breeding programs have been using non-adapted parent to incorporate resistance to Fusarium head blight caused by *Fusarium graminearum* (Miedaner et al., 2006) and other diseases. However, the domesticated crops are narrowing their germplasm base (Zamir, 2001) decreasing their ability to adapt to emerging biotic and abiotic stresses and increasing potential for widespread crop failure (Horsfall et al., 1972). The exotic germplasm can be used as a source of genetic variation lost during the domestication. These non-adapted genotypes, including wild species and landraces, often carry agronomically undesirable alleles. However, genetic studies can identify the valuable genes from the exotic species, and integrate these traits into released varieties (Zamir, 2001).

### **Kernel characteristics**

In recent years, scientists (Dholakia et al., 2003; Breseghello and Sorrells, 2007; Sun et al., 2009) have been studying traits to be used as markers for indirect selection for yield as well as quality. The major components of wheat grain yield are productive spikes per unit area, kernels per spike, and kernel weight. Other traits that can affect kernel number are tillers per plant, spikelets number per spike, and number of viable florets per spikelet (Ma et al., 2007). Since kernel is the main component of wheat grain yield, researchers are interested in studying the properties of kernel characteristics and their genetics. Similarly, they are trying to determine the relationship between kernel traits and wheat quality and agronomic traits. An example is the association between kernel size and seedling vigor. Larger seeds could have a positive association with seedling vigor and,

consequently, increased grain yield. Recently, Breseghello and Sorrells (2007) found that kernel size and shape can contribute to the improvement of grain yield and quality of the final product. In addition, similar results were found by Gaines et al. (1997), showing that size, shape, and consistency of kernels is essential to flour yield, an important trait for the milling industry. The importance of choosing the right variety with the most desirable characteristics for quality attributes has been reinforced by Souza et al. (2004), which found that the genotype selection is more crucial for high quality wheat than environment conditions and nitrogen levels.

Most of the biological characteristics for important kernel traits, such as wheat kernel size, are complex and believed to be genetically quantitative (Campbell et al., 1999; Sun et al., 2009). In addition, wheat kernel characteristics are frequently influenced by environment, having high genotype x environment interaction (Sun et al., 2009). Dholakia et al. (2003) using a population of 106 F<sub>7</sub> recombinant inbred lines (RIL), generated from a cross between the two hexaploid wheat cultivars PH 132 and WL 711, concluded that the kernel length, weight, width and the factor form density (FFD) parameter described by Giura and Saulescu (1996) have polygenic nature. The FFD was expressed as:  $FFD = \text{kernel weight} / (\text{kernel length} \times \text{kernel width})$ . Their conclusion was based on the continuous variation obtained for these traits. They also observed transgressive segregants for all kernel traits.

Different characteristics such as kernel volume weight or test weight, grain density, kernel sizing, near-infrared reflectance, hardness score among others have been tested for wheat physical quality. Wheat kernel weight and size are important quality factors for evaluation of milling characteristics (Ohm et al., 1998). Kernel volume weight is

considered by semolina millers to be a desirable physical trait in wheat, along with kernel size, vitreousness, and cleanliness (Troccoli and Di Fonzo, 1999).

Kernel characteristics, texture, kernel volume weight, shape of germ, crease, and brush are characteristics that can influence milling quality, which affects the market value of wheat. For bread wheat, kernel shape and uniformity can significantly affect milling quality (Campbell et al., 1999). Gaines et al. (1997) reviewed the effect of kernel size on milling quality in wheat. They found considerable diversity in kernel size among the soft wheat cultivars based on their average kernel size and on the range of kernel size distribution. This is evidenced by some large kernel varieties being twice as large as small kernel varieties. They also reported that there is variation in kernel diameter and weight. The pressure on the development of modern cultivars with superior grain yield can result in wheat cultivars with smaller average kernel size and a wider size range. Gaines et al. (1997) believed that this may happen because modern varieties are released to produce smaller tertiary kernels between two rows of full-size kernels. However, tertiary kernels do not fill out completely during the grain filling period because they have less time to develop, thus they can be shriveled or smaller.

Millers realized that milling a mixture of small and large kernels on a roller mill reduces the flour yield because the break roll gap setting cannot be optimized for either the small or the large kernels (Gaines et al., 1997). Preferably, the break roll spacing in this situation should be set for the average kernel size. Since size mixtures are normal and there is a tendency to associate small kernels with shriveled grains, small kernels are frequently considered to have less flour yield potential and therefore are considered to have lower milling properties. Cleaning (aspiration or sieving) grains to remove shriveled kernels,

usually results in increased homogeneity. However, this cleaning will result in economic loss in quantity because small yet sound and good quality kernels are also discarded. Millers should pay attention to small kernels if they wish to have a high quality mill. A possible solution to improve milling wheat with different kernel size could be, first, to classify and subdivide kernels according to their size, then mill kernels with different kernel sizes separately (Gaines et al., 1997).

Different approaches have been used to study the shape and size of wheat kernels. Marshall et al. (1984), using geometrical models based on theoretical analyses, classified this technique as being precise. The conclusion was drawn because both shape and kernel size can significantly affect the volume per unit surface area of the wheat kernel, consequently milling yield and proportion of flour per unit weight of kernel. They found that the best shape to increase milling yield is a spheroid shape, which unfortunately is negatively correlated to grain yield. However, the same authors added that the geometrical model is not yet realistic, and that further studies should be conducted. For breeding purposes, changes in kernel volume weight have a greater impact on milling yield than changes in kernel shape. Furthermore, kernel volume appears to be easier to manipulate in plant breeding programs than kernel shape. However, breeders should take into consideration the impact of selection for kernel characteristics on yield and quality (Marshall et al., 1984).

Kernel volume weight has been shown to be an important trait for growers and millers (Marshall et al., 1984; Gaines et al., 1997; Campbell et al., 1999; Breseghello and Sorrells, 2007; Sun et al., 2009). It is highly correlated to kernel characteristics and has a higher heritability compared to grain yield. Kernel volume weight is utilized in breeding

programs in order to discard lines in early generations (Patil et al., 1994). In addition, kernel volume weight has demonstrated a high positive correlation with flour quantity. Also, it has been used as an indicator of overall grain quality and it is utilized to establish the price in several countries (Sun et al., 2009).

### **Kernel characteristics evaluation methodologies**

Efficient, precise, realistic, and simple techniques to measure the kernel traits should be used with the intention to understand better the kernel characteristics and how they could generate gains on agronomic traits such as grain yield or quality traits such as kernel volume weight or flour extraction.

Currently, the techniques used are:

- Theoretical geometric model – it is a geometrical model based on theoretical analysis. In this method, there is no use of kernels, thus it was classified by the authors (Marshall et al., 1984) as unrealistic, although, precise. It was used to predict the best shape and size of wheat kernel to enhance flour extraction.
- Kernel size distribution – kernels are separated into three classes; large, medium, and small. Usually, the distribution is done by a wheat sizer equipped with three sieve openings. Top sieve (Tyler #7 with 2.92 mm opening), middle sieve (Tyler #9 with 2.24 mm opening), and bottom sieve (Tyler #12 with 1.65 mm opening). This technique has been used for many years. However, there are no specific measurements of kernel dimension. Several researchers have used this technique (Gaines et., 1997; Ohm et al., 1998; Tsilo et al., 2010).
- Manual – researchers have evaluated kernel length and width using a ruler with precision of 0.1mm (Sun et al., 2009). Another possibility to measure kernel

length and width is the use of Vernier Calipers (Dholakia et al., 2003). This technique can take a long time to evaluate the samples and can have a low precision especially when low amount of kernels are evaluated (usually between 20 and 30 kernels).

- Single kernel characterization system (SKCS) – the SKCS 4100 (Perten Instruments, Springfield, IL) instrument was created at the USDA Grain Marketing and Production Research Center in Manhattan, KS (Osborne and Anderssen, 2003). The SKCS was mainly developed for kernel hardness measurement. However, it also provides kernel weight and width but not kernel length. These features have been added lately as well (Ohm et al., 1998; Lee et al., 2006; and Tsilo et al., 2010).
- Digital image analysis - basically, this evaluation technique consists of three steps. First, a photograph of the kernel sample is taken. Second, this photograph is processed to be able to run in the next program (in some systems the second step is skipped). Third, the processed photograph is analyzed by a program that provides the kernel measurements. Usually, it can measure the kernel length, width, and area. However, it can require a long time to complete all the procedures. There are few studies using digital image analysis technology to measure kernel traits (Campbell et al., 1999; Bergman et al., 2000; Breseghello and Sorrels, 2006; and Breseghello and Sorrels, 2007).

Currently, the available techniques to measure kernel dimensions lack at least one of the principles to be an ideal model. This model has to be efficient, precise, realistic,

simple, and provide all kernel dimensions. Consequently, future efforts should take place on the development of new techniques that incorporate all requirements for an ideal model.

### **Genetics of kernel characteristics**

Dholakia et al. (2003) in their molecular studies on kernel length, weight, width and FFD found that nine markers were associated with kernel length. These markers consisted of five Microsatellite (MS), three Random Amplification of Polymorphic DNA (RAPD), and one Inter Simple Sequence Repeat (ISSR). Two markers were localized on chromosome 2BL, two on chromosome 2DL, one on chromosome 5BL, one on chromosome 6BS, and one on chromosome 7BL. The localization of the remaining two markers was not determined. For kernel weight, seven markers were found: three ISSR, two RAPD, and two MS. Three markers were located on chromosome 2BL, two on chromosome 2DL, and two markers were not localized. In the same study, only two markers were found to be linked to kernel width. One of them was located on chromosome 2DL, and the other was not localized. Six markers were associated with the FFD parameter: four MS, one ISSR, and one RAPD. Two markers were located on chromosome 2DL, one on 5BL, one on 6BS, and the other two markers were not localized.

The same study (Dholakia et al., 2003) indicated that some markers were correlated with several traits. For instance, the marker located on chromosome 2DL for kernel width was also linked to kernel length, weight and FFD. Similarly, for FFD markers, one was associated with all other traits, two markers were associated with kernel length and weight, and two associated with kernel length. Based on the association among these loci, it was proposed that they may have pleiotropic effects on kernel characteristics, or they are tightly linked loci.

Other molecular studies have been conducted to investigate the genetics of kernel characteristics. Breseghello and Sorrells (2007), among others, located several loci on chromosomes 2D, 5A, and 5B as having major effects on kernel size and shape in wheat. These researchers referred to measurement of kernel size using traits such as kernel projection area, cross-section area, surface, volume, and weight. Kernel shape was measured by these researchers using characteristics such as kernel length, width, horizontal axes proportion, sphericity and vertical perimeter.

### **Correlation among wheat characteristics**

Sun et al. (2009) conducted a study using a set of 131 RIL derived from a cross between two Chinese lines (Chuan 35050 x Shannong 483) and they found positive correlation between kernel length and kernel width, and kernel weight (0.216, and 0.424, respectively). Kernel weight and kernel width, and kernel volume weight were also correlated (0.753 and 0.194, respectively). A negative correlation was detected between kernel volume weight and kernel length (-0.222). Kernel volume weight and kernel width had no significant correlation.

In another study conducted by Ohm and his co-researchers (1998), flour yield was significantly correlated with kernel hardness, volume weight, and density (0.50, 0.50, and 0.36, respectively). Large kernel had no significant correlation with flour yield. Contrary to other findings (Troccoli and Di Fonzo, 1999), Ohm et al. (1998) also reported significant positive correlation between kernel volume weight and kernel weight (0.47). However, the positive correlation among these characteristics can be due to environmental effects (Ghaderi and Everson, 1971). Slaughter et al. (1992), Satumbaga et al. (1995) and Ohm et al. (1998) found negative correlations between protein content and wheat kernel size and

weight. According to Morris et al (1946) wheat with heavier and thicker kernels could have a higher portion of endosperm which contains lower amounts of protein content than the aleurone layer.

Therefore, many aspects related to kernel characteristics remain unclear. This study aimed to examine the kernel characteristics, their associations, and explore the potential use of genetically diverse and non-adapted germplasm, to improve agronomic and quality traits in breeding programs, in order to develop new cultivars with high yield and quality attributes, and increase the germplasm base.

**PAPER 1. WHEAT AGRONOMIC AND QUALITY TRAITS VARIATIONS,  
CORRELATIONS, AND POTENTIAL IMPROVEMENT FROM CROSSES OF  
ELITE X NON-ADAPTED GERMPLASM**

## ABSTRACT

Wheat improvement has been in most of the cases accompanied by a narrowing germplasm base, as newer cultivars have been derived from intercrosses between elite germplasm. However, there is a concern that narrow germplasm may restrict breeding improvement for important traits such as resistances to new biotic and abiotic stresses in the future. With the intention to broaden the wheat germplasm, a two-year study was initiated in 2009 to examine the agronomic and quality attributes of 160 Recombinant Inbred Lines (RIL) developed from an adapted line (ND 705) and a non-adapted genotype (PI 414566). The experiment was conducted at Prosper and Carrington, North Dakota, during two years. The RIL population had a better performance at Carrington due to favorable climatic conditions at this location, in 2009 and 2010. Eight RIL yielded better than the adapted parent ND 705 and two of the RIL along with three checks were significantly superior for grain yield compared to the other genotypes across all environments. Although the non-adapted parent has a facultative grown habit, several RIL required fewer days to flower compared to the adapted parent. Two RIL had better flour extraction compared to the other genotypes included in this study. This RIL population had also many lines with poor agronomic and quality performance. However, the high agronomic and quality attributes showed by some RIL demonstrated that the use of a non-adapted parent can broaden the genetic variability while increasing the genetic gain for some traits.

## INTRODUCTION

Wheat (*Triticum aestivum* L.) is one of the most important staple foods in the world. In 2010, wheat had a global production of 645.4 million tons. The USA is the largest wheat exporter with 28 % of the world exports. However, the wheat production in the USA has decreased. China and India are the largest wheat producers in the world. The Russian wheat production increased drastically in the last years exceeding the USA production which is the fourth largest wheat producer in the world (USDA-ERS, 2011).

Wheat in the USA has entered the 21<sup>st</sup> century dealing with many challenges, despite a strong domestic market for wheat products. This happened for many reasons including the following. First, wheat returns decreased compared with other crops, stemming in large part from foreign competition. Second, the government programs provide more support to alternative crops. Consequently, wheat acreage harvested has decreased nearly by 12 million ha (35 %) of its highest acreages reached in 1981. The USA wheat export share percentage has also declined in the past two decades (USDA-ERS, 2011).

Along with rice, wheat is the main source of energy for human beings. Wheat is an inexpensive source of carbohydrates, fiber, protein and vitamins. Wheat is used as raw material in making breads, cakes, cookies, pastries, crackers, and in the manufacturing of pasta products such as macaroni and spaghetti. Breeders aim to increase wheat grain yield and quality attributes while keeping it easy to access and inexpensive. Researchers in recent studies (Souza et al., 2004; Otteson et al., 2007; Otteson et al., 2008) tested different factors such as genotype, environment conditions, nitrogen level, and timing, and seeding rate that could influence grain yield and its quality aspects. They found that genotype

selection was the most important factor in determining grain yield and quality, including milling performance.

Alexander et al. (1984) studied the effects of yield component selection on wheat grain yield in three populations. They found that selection for kernel weight has usually enhanced grain yield. They also indicated that using kernel weight could be a desirable trait in early generation selection because this trait can generally be measured with more precision at relatively low cost. However, direct selection for grain yield was usually more effective showing that an optimum balance between the number of spikes per unit area, kernels per spike, and kernel weight may possibly result in high yielding genotypes. Baril (1992) working with 34 winter wheat genotypes also found that kernel weight was the most important yield component.

Bread wheat quality is a key attribute for wheat milling and baking industry exigencies and broad consumer preferences. Bread wheat has to meet requirements of domestic and export markets. Therefore, end-use quality has been one of the major targets of various wheat breeding programs around the world, especially in Australia, Canada, and USA. Wheat consumers and baking industries are becoming more exigent for wheat quality attributes. Breeders usually focusing on grain yield and resistance/tolerance for abiotic and/or biotic stresses are currently placing more emphasis on quality characteristics (Marshall et al., 1984; Nelson et al., 2006; Kerfal et al., 2010). Some of the indicators for milling quality include kernel volume weight, 1000-kernel weight, and flour extraction yield (Finney et al., 1987). Currently, several quality traits such as grain protein content and kernel volume weight are being used routinely as markers for indirect selection for quality (Nelson et al., 2006).

Milling quality is a function of the proportions of flour extracted and the flour contamination by non-endospermic tissues (brain and germ) of the wheat kernel (Marshall et al., 1984). However, desirable quality attributes vary according to the final use of the wheat flour. Suitable bread production requires cultivars with higher protein concentration, alkaline water retention capacity, and dough strength whereas for cakes and cookies these traits are undesirable (Nelson et al., 2006).

Hard red spring wheat (HRSW) grown in the Northern Great Plains of North America is a premium class of wheat used in end-use purposes requiring high gluten strength. Flour mills worldwide blend HRSW with other wheat classes with lower protein to enhance the gluten strength. These flour blends formed by different concentrations of HRSW are used to classify bread products and Chinese-type noodles. In addition, products such as whole grain breads, pizza crusts, yeast breads, hard rolls, and bagels, produced with HRSW display superior appearance and taste (Underdahl et al., 2008a).

Wheat improvement has been in most of the cases accompanied by a narrowing germplasm base, as newer cultivars have been derived from intercrosses of existing elite germplasm. Wheat breeding programs are continuously improving and releasing varieties with higher agronomic and quality attributes with the use of narrow germplasm base. However, there is a concern that narrow germplasm may restrict breeding flexibility and slow response to new biotic and abiotic stresses. Also, the tendency of the continuous use of the same germplasm base will at a certain point of time result in an even more restrict germplasm base. Due to these restrictions, many wheat breeding programs are broadening the genetic diversity using elite x exotic crosses (Holley and Goodman, 1988). The utilization of exotic germplasm is usually undesirable by breeders due to its non-

adaptability. The reason for this is that favorable attributes are often linked to undesirable traits in non-adapted germplasm and it is difficult to dissociate them. These linked groups are called linkage drag (Stalker 1980; Patterson et al. 1991). A complete integration of exotic and elite chromosomes is required to avoid the loss of useful linked factors. Several generations of random mating, with or without mild selection, are recommended before the application of more rigorous selection (Eagles and Lothrop, 1994).

The exotic germplasm can be used as a source of genetic variation lost during the domestication and selection. These non-adapted genotypes, including wild species and landraces, often carry undesirable alleles. However, genetic studies can identify the agronomic valuable genes of the exotic species, and integrate these traits into released varieties (Zamir, 2001) increasing the genetic variability thereby preventing widespread crop failure.

Therefore, many aspects related to elite x non-adapted (exotic) crosses remain unclear requiring further investigations. The objectives of this study were to explore the possibility to improve the agronomic and quality traits with the use of a cross between elite x non-adapted germplasm and explore the potential use of exotic germplasm in breeding programs, in order to develop new superior germplasm.

## MATERIAL AND METHODS

### Material

This study was conducted using a population of 160 RIL. This population was developed from a cross between ND 705 and PI 414566. The ND 705 is a HRSW line developed by the HRSW breeding program at North Dakota State University (NDSU). The PI 414566 is originally from China and it was obtained from the USDA National Small Grains Collection. It is described as a facultative type of wheat which requires cold temperature to flower, tall, brown kernels, and susceptible for diseases such as stripe rust caused by *Puccinia striiformis*. The RIL population was advanced through single seed descent method to F<sub>8</sub> generation and it was obtained from the Wheat Germplasm Enhancement program at NDSU. A combination of field nurseries at New Zealand, North Dakota, and greenhouse were used to advance this population. The selection of the parents used to develop this RIL population was based on the genetic divergence between the parents in order to produce a RIL population with significant polymorphism for agronomic and quality traits. The number of RIL used in this study was determined by the amount of seeds available for each RIL.

The checks used in this study were: 'Alsen' (PI 615543) (Frohberg et al., 2006), 'Steele-ND' (PI 634981) (Mergoum et al., 2005), 'Glenn' (PI 639273) (Mergoum et al., 2006), 'Faller' (PI 648350) (Mergoum et al., 2008), 'Barlow' (PI 658018) (Mergoum et al., 2011), 'Briggs' (PI 632970) (Devkota et al., 2007), and 'Alpine'. All the check cultivars are HRSW varieties except Alpine which is a hard white spring wheat variety.

## Field experiment

The RIL, their parents (ND 705 and PI 414566), and checks (Alsen, Steele-ND, Glenn, Faller, Barlow, Briggs, and Alpine) were evaluated in the summers of 2009 and 2010 at two field locations in ND; Carrington Research Extension Center near Carrington and Prosper Research Plots near Prosper. These sites represent two diverse environments. Carrington is located in the Central ND region with an altitude of 484 m. The soil type at Carrington is Heimdal-Emrick series (loamy, mixed, superactive, Calcic/Hapludolls). Prosper is located in the Red River Valley region (Eastern ND) with an altitude of 274 m. The soil type at Prosper is Bearden series (fine silty, mixed, superactive, frigid Aeric Calciaquolls) (USDA-NRCS, 2011).

In 2009, the planting dates were May 7 at Carrington, and May 28 at Prosper. The harvesting dates were August 26 at Carrington for all the lines except the parent PI 414566 which was harvested on October 6. At Prosper all the lines were harvested on September 18 except PI 414566 which was harvested on October 13. The winter of 2008-2009 had a high amount of snow causing field flood delaying the planting date. Consequently, PI 414566 as a facultative type requiring a longer period to complete its cycle did not have enough cold temperature to completely flowering. In 2010, the planting dates were April 21 at Carrington, and May 20 at Prosper. The harvesting dates were August 18 and 27 at Carrington and Prosper, respectively. PI 414566 was vernalized for three weeks prior to planting at Prosper. However, the emergence rate of the PI 414566 vernalized seeds was very low because of the poor and heavy soil characteristics at Prosper in 2010. Carrington was planted earlier; consequently, PI 414566 had enough cold temperature to flower,

therefore completing its cycle successfully. Sowing rates was  $113 \text{ kg ha}^{-1}$  in all environments.

In 2009, the experiments included the  $F_{8:9}$  RIL, their parents, and checks. In fall 2009, the RIL were sent to New Zealand winter nursery for seed increase. Consequently, in 2010, the experiments included the  $F_{10:11}$  RIL, their parents, and checks. The entries were arranged in a  $13 \times 13$  partially balanced square lattice design, with two replicates. The experimental units consisted of seven rows, 2.44 m long and 12.7 cm apart.

### **Data collection**

The grains from harvested plots were cleaned by using a clipper grain cleaner before measuring the following traits.

#### **Agronomic traits**

- Grain yield ( $\text{kg ha}^{-1}$ ) – determined by weighing the cleaned grain harvested from each plot.
- Yield components:
  - ✓ Number of spikes ( $\text{spikes m}^{-2}$ ) – determined by counting the number of spikes in two 61 cm long rows per plot. Counts were then converted to determine total number of spikes per square meter.
  - ✓ Number of kernels ( $\text{kernels spike}^{-1}$ ) – calculated by averaging the kernels from ten individual spikes selected at random from each plot. The kernels were counted by the electronic seed counter (Seedburo Equipment Co., Chicago, IL) after threshing the spikes.
  - ✓ 1000-kernel weight (g) determined by ‘Digital Image Analysis’ (DIA) – calculated based on the number of kernels within 10 g samples from each

plot used in the DIA. The results were converted and the weight of 1000 kernels was determined (Doehlert et al., 2004).

- Plant height (cm) – measured from the soil surface to the top of the spike, excluding the awns at maturity. An average plant height was recorded from each plot.
- Days to heading (days) – recorded when inflorescences fully emerged in at least 50% of the spikes and was calculated as the number of days from planting to heading.
- Lodging (%) – estimated by the percent of lodged plants per plot when lodging occurred at a given environment.
- Maturity (days) – recorded when kernels fully complete the physiologic maturity in at least 50 % of the spikes. It was calculated as the number of days from planting to maturity.
- Emergence (%) – estimated by the percent of fully emerged plants per plot.
- Spike color (1-5) – visually rated by using a scale having equidistant values from 1 (white) to 5 (dark red).

#### **Quality traits**

- Grain protein content (%) – measured according to American Association of Cereal Chemists (AACC) standard method 46-30 (AACC International, 2000), using an Infratec 1226 Cold Grain Analyzer expressed on a 12 percent basis.
- Kernel volume weight ( $\text{kg m}^{-3}$ ) – measured according to AACC standard method 55-10 (AACC International, 2000).

- Kernel hardness (0-90+) – measured using the single kernel characterization system (SKCS) 4100 instrument (Perten Instruments, Springfield, IL). This instrument measured the force needed to crush the kernels which is expressed as a hardness index. Table 1 has the kernel hardness category classification according to the hardness index.

Table 1. Kernel hardness category classification according to the hardness index (HI)

| Category    | HI <sup>a</sup> |
|-------------|-----------------|
| Extra hard  | 90 +            |
| Very hard   | 81 – 90         |
| Hard        | 65 – 80         |
| Medium hard | 45 – 64         |
| Medium soft | 35 – 44         |
| Soft        | 25 – 34         |
| Very soft   | 10 – 24         |
| Extra soft  | Up to 10        |

<sup>a</sup> HI=hardness index

- Flour extraction (%) – 150 g cleaned wheat samples were tempered to 16.0 % moisture for 16 hr before being milled on a Brabender Quadrumat Junior Mill according to standard procedure used at the Department of Cereal and Food Sciences at North Dakota State University. The flour extraction percentage was calculated by dividing the flour weight of straight grade flour over the total grain weight milled (150 g).

### Data analysis

Data were subjected to the analyses of variance (ANOVA), using the MIXED procedure of the Statistical Analyses System (SAS Institute, 2004). Within the mixed model, the RIL, their parents, and checks were considered fixed effects. Environments and blocks were considered random effects. The ANOVA was conducted within and across

environments. Environments were considered homogeneous when the ratio of the effective error variances for each trait was less than 10-fold (Appendix Table 1) (Hartley, 1950; Patterson and Silvey, 1980; Geng et al., 1982; Mitchell, 1995). Data were subjected to combined analysis if environments were homogeneous. Tables 2 and 3 show the pertinent sources of variation, degrees of freedom, and the appropriate expected mean squares.

Table 2. Single analyses of variance for a lattice design, with treatment as fixed effects, and rep as random effects

| SOV               | DF <sup>a</sup>       | MEAN SQUARE |                                      | F-test    |
|-------------------|-----------------------|-------------|--------------------------------------|-----------|
|                   |                       | Obs         | Expected                             |           |
| Rep               | $r - 1$               | M1          |                                      | non-valid |
| Blocks within rep | $r(k - 1)$            | M2          |                                      | non-valid |
| Treatment         | $(t - 1)$             | M3          | $\sigma^2 + r\sum\alpha_i^2 / (t-1)$ | M3 / M4   |
| Error             | $(k - 1)(rk - k - 1)$ | M4          | $\sigma^2$                           |           |
| Total             | $rk^2 - 1$            |             |                                      |           |

<sup>a</sup> = The letters k, t, and r refer to the size of the lattice, the number of treatments, and the number of replications, respectively.

Table 3. Combined analyses of variance for a lattice design, across 2 years and 2 locations, with treatment as fixed effects, and rep and environment (year x location) as random effects

| SOV                    | DF <sup>a</sup>        | MEAN SQUARE |  | F-test    |
|------------------------|------------------------|-------------|--|-----------|
|                        |                        | Obs         | Expected   |           |
| Environment            | $e - 1$                | M1          |  | non-valid |
| Treatment              | $t - 1$                | M2          | $\sigma^2 + r\sigma_{et}^2 + re\sum\alpha_i^2 / (t-1)$ | M2 / M5   |
| Rep within Env         | $e(r - 1)$             | M3          |  | non-valid |
| Block within Rep x Env | $er(k - 1)$            | M4          |  | non-valid |
| Env x Treat            | $(e - 1)(t - 1)$       | M5          | $\sigma^2 + r\sigma_{et}^2$                            | M5 / M6   |
| Error                  | $e(k - 1)(rk - k - 1)$ | M6          | $\sigma^2$   |           |
| Total                  | $ert - 1$              |             |  |           |

<sup>a</sup> = The letters k, t, e, and r refer to the size of the lattice, the number of treatments, the number of environments, and the number of replications per environment, respectively.

Mean separation test was performed using an F-protected least significant difference (LSD) value at  $P \leq 0.05$  level of significance for each trait. Correlations between the different agronomic and quality traits were calculated for single

environments using the CORR procedure of SAS (2004). Pooled correlations were determined in case of homogeneous correlations. The homogeneity test of the correlations was determined using the  $\chi^2$ .

## RESULTS AND DISCUSSION

### Climatic conditions

The 2009 growing season at Carrington and Prosper was characterized by lower rainfall and colder temperatures compared to 2010 growing season and the long term average. Prosper 2010 had the highest amount of rainfall and air temperature in all four environments (Table 4). Prosper, however suffered with a strong hail storm and wind in both years decreasing significantly wheat grain yield and quality attributes especially for the RIL population due to lodging. Climatic conditions at Carrington were in general favorable for spring wheat in both 2009 and 2010. Carrington in 2010 was the earliest planted experiment (21 April) in all environments. The cold weather during the emergence and early wheat growing stages allowed the facultative parent PI 414566 to flower and complete its growing cycle.

Wheat worldwide is classified into two distinct groups according to the vernalization requirements: winter and spring types. Generally, winter wheat requires cold temperature or vernalization period to be able to flower while spring wheat is normally insensitive to cold temperature. However, there are intermediate wheat types which require cold temperatures classified in between winter and spring types. These intermediates types of wheat are called semi-winter, alternative, or facultative. PI 414566 turns out to be one of these wheat types. According to Stelmakh (1998), they are usually characterized by strong photosensitivity and partial sensitivity to vernalization. Facultative wheats have in general less cold tolerance, a shorter but distinct period required for vernalization, and flower earlier compared to true winter wheats (Stelmakh, 1998). Based on 2009 results (low productivity of PI 414566) the seeds of the parent PI 414566 were germinated and

vernalized prior to planting at Prosper in 2010. Unfortunately, seedling survival rate after transplanting was very low (18%) due to the heavy soil (Bearden series) at Prosper.

<sup>a</sup> Total rainfall and air temperature of the long term averages measured since 1990 (Source: NDAWN, 2011).

## Data analysis

The ANOVA for each environment was performed. The error variance was homogeneous across all environments allowing a combined analysis across the four environments for all the traits except lodging. The homogeneity test was performed based on the 10-fold concept (Appendix 1). The ANOVA summaries for the agronomic and quality traits are reported in Table 5, while the means of the experiment, parents, RIL, and checks for the combined and single environments are presented in Table 6. The ANOVA (Table 5) shows that the genotypes variances were significant for all the agronomic and quality traits. The environments also had a significant effect on all traits.

Table 5. Source of variation, degrees of freedom, mean square, and level of significant of the agronomic and quality traits of the RIL, their parents, and checks grown at Carrington and Prosper, ND, during 2009 and 2010

- Traits were not collected at these locations.

The treatment x environment interactions were significant for all agronomic and quality traits as well. At Carrington, the genotypes performed overall much better for most agronomic and quality trait as compared to Prosper. Within the locations, the genotypes had a better performance in 2009 compared to 2010. The parents, ND 705 and PI 414566, showed drastic differences for all the agronomic and quality traits with ND 705 being

superior for all traits (Table 6). This confirmed the decision to develop a RIL population with large diversity, thereby broadening the genetic range due to the use of an elite x exotic type of cross.

## **Agronomic traits**

### **Grain yield**

Considerable segregation was observed for the agronomic traits including grain yield for the RIL population. Grain yield followed relatively a normal distribution (Figure 1), suggesting polygenic inheritance. The mean grain yield overall environments was 3042 kg ha<sup>-1</sup>. While the RIL population mean for yield across environments was 3002 kg ha<sup>-1</sup>, ND 705 and PI 414566 parental means were 3581 and 615 kg ha<sup>-1</sup>, respectively. The grain yield mean for checks across environments was 4236 kg ha<sup>-1</sup> (Table 6). The checks Faller, Barlow, and Steele-ND, and the RIL 143 and 88 were significantly superior compared to the other genotypes across environments. Faller was the only genotype that had significantly superior yield in all the environments while Barlow and Steele-ND were not significantly superior at Prosper in 2010. The RIL 143 and 88 were among the group that had significantly higher grain yield at two of the four environments (RIL 143 at Carrington and Prosper in 2009, and RIL 88 at Prosper in 2009 and Carrington in 2010) (Table 7). In addition to diseases (mainly Fusarium head blight caused by *Fusarium graminearum* and leaf diseases) lodging and kernel shattering were other main reasons for decreased grain yield especially at Prosper in 2010. Barlow and Steele-ND also had losses in grain yield due to lodging and kernel shattering. Barlow and Steele-ND had 7 and 16 % lodging, respectively, and relatively low kernel shattering, while RIL 143 and 88 had losses in grain yield due to lodging. RIL 143 and 88 had 11 and 24 % lodging, respectively.

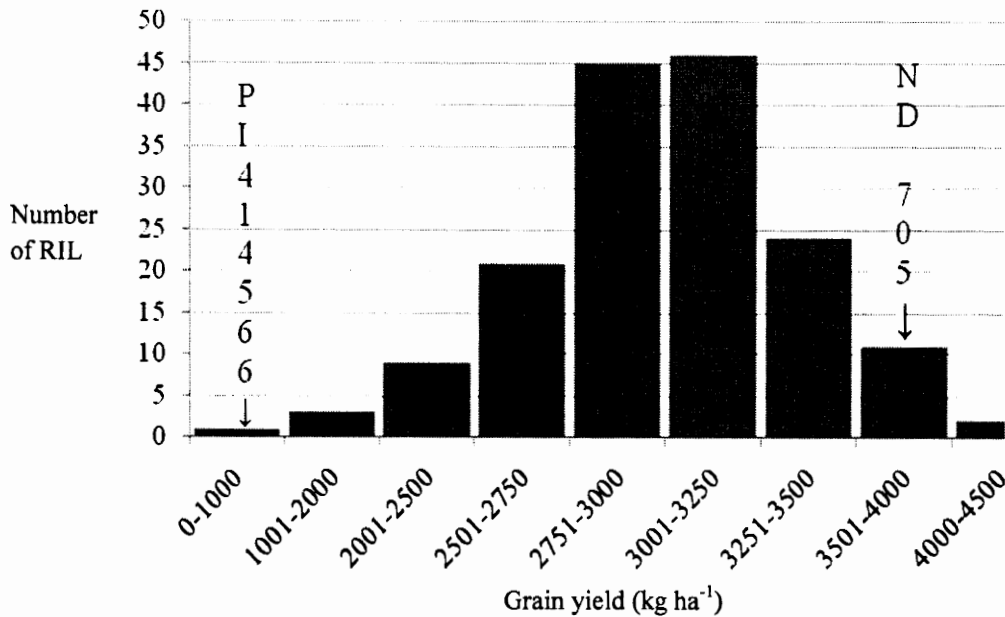

Figure 1. Frequency distribution of 160 RIL and their parents for mean grain yield across all locations (Carrington and Prosper, ND) and years (2009 and 2010). (Parental means are marked with arrows).

PI 414566 had significantly the poorest performance for grain yield in all environments. This parent was not able to complete its cycle in 2009, and had low emergence rate (18 %) and high lodging percentage (62 %) at Prosper in 2010 (Table 6). Three RIL (106, 127, and 96) had also poor performance in at least three out of the four environments (Table 7). These three RIL had also high lodging percentage (100, 80, and 88 % at Prosper in 2010; 56, 55, and 43 % at Prosper 2009; respectively). At Carrington, only RIL 106 had lodging problem (38 %) in 2010. PI 414566 was more susceptible to diseases overall than the adapted parent ND 705. Probably the RIL with low grain yield incorporated the susceptible genes for diseases from the non-adapted parent PI 414566. This could be another factor that resulted in low grain yield for these RIL.

PI 414566, a facultative type of wheat, even with adequate growing conditions at Carrington in 2010 had poor agronomic performance. ND 705, an experimental line, was

Table 7. Grain yield means (kg ha<sup>-1</sup>) and least square difference (LSD) of the top and bottom ten genotypes across all environments (Carrington and Prosper in 2009 and 2010)

<sup>a</sup> GY=grain yield, kg ha<sup>-1</sup>.

not released by the HRSW Program, although it went to the last steps of the breeding pipeline demonstrating its high agronomic performance. Most RIL had a grain yield performance ranging between the two parents or statistically equal to ND 705. However, eight RIL yielded better than the best parent indicating transgressive segregation for grain yield in this population. This demonstrates the possibility of selecting genotypes with high yield better than the best parent.

Tsilo et al. (2010) in their study used two well adapted hard red spring wheat lines, MN98550 (Bacup/McVey) and MN99394 (SD3236/SBF0402), to generate 139 RIL population. These parents diverged for water absorption and dough mixing strength. Both parents performed well and very similar for grain yield. However, they were also able to observe transgressive segregation on their RIL population for grain yield. The range for grain yield among their RIL population however, was smaller compared to the RIL used in our study. This can be due to a lack of genetic variation between the RIL parents in their study. McCartney et al. (2005) worked with a population originating from two parents yielding identically. Consequently the segregation for yield was smaller as well. The use of a non-adapted line as one of the parents crossed with an adapted line theoretically should increase the segregation of the population for several traits. However, the chance to find RIL with higher grain yield than the best parent is usually rare because of the undesirable linkages or unfavorable alleles for high performance (in this case yield) that come from the non-adapted parent. However, crosses between elite x elite lines usually should generate progenies with better agronomic performance. In most of the RIL population originated from elite x non-adapted lines, back-crosses to the adapted parent are required; however, in this study the eight superior RIL showed that after several generations of recombination,

outstanding lines can be obtained from a cross between elite (ND 705) x non-adapted (PI 414566). Similarly, many RIL in this population had low grain yield.

### **1000-kernel weight**

The three most important yield components are 1000-kernel weight, number of kernels/spike and number of spikes/m<sup>2</sup>. The mean for 1000-kernel weight over the four environments was 28.4 g. ND 705, PI 414566, RIL, and checks means were 30.1, 16.0, 28.4, and 31.2 g, respectively. The range among RIL was from 22.4 to 35.1 g (Table 6). Among the RIL, 37 had heavier kernels compared to ND 705 indicating transgressive segregation for this trait as well. The only top yield cultivar among the group with the largest values of 1000-kernel weight was Faller. The other checks and top RIL for grain yield were among the intermediate, close to the superior group, while all the poor yielding RIL (106, 127, and 96) and PI 414566 were among the bottom group with low 1000-kernel weight. As expected, the 1000-kernel weight was positively correlated with grain yield in all environments. The correlation coefficient values for Carrington and Prosper in 2009 were homogeneous and were pooled together ( $r=0.44$ ). However, non-pooled correlations for Carrington and Prosper in 2010 were 0.19, and 0.75, respectively (Table 8). Similar results were reported by Hsu and Walton (1971), and McCartney et al. (2005) who found a significant correlation between 1000-kernel weight and grain yield. However, Tsilo et al. (2010) did not find significant association between these two traits. Large genetic diversity was observed for this trait facilitating selection. However, it is well known that yield components compensate for each other. Therefore, grain yield is often a function of well balanced yield components. Selecting only for kernel weight does not result in lines with the highest grain yield.

Table 8. Correlation coefficients (r) among grain yield and yield components (1000-kernel weight, number of kernels per spike, and number of spikes per m<sup>2</sup>) and their significance for the RIL, their parents, and checks grown in four environments (Carrington 2009 and 2010, and Prosper 2009 and 2010). The homogenous r values were pooled and denoted in the table

|             | Environment | 1000-kernel weight  | Number of kernels/spike | Number of spikes/m <sup>2</sup> |
|-------------|-------------|---------------------|-------------------------|---------------------------------|
| Grain yield | Carr 09     | 0.44** <sup>a</sup> | 0.24** <sup>a</sup>     | 0.43** <sup>a</sup>             |
|             | Pros 09     |                     |                         |                                 |
|             | Carr 10     | 0.19*               |                         |                                 |
|             | Pros 10     | 0.75**              | 0.57**                  |                                 |

\* and \*\* Significant at the 0.05 and 0.01 probability levels, respectively.

<sup>a</sup> Pooled correlation coefficients across environments.

### Number of kernels/spike

The overall mean for number of kernels/spike was 34. ND 705, PI 414566, and RIL means were 30, 27, and 34 kernels/spike, respectively. The range among RIL was from 27 to 42 kernels/spike. The overall mean of the checks for number of kernels/spike was 32 (Table 6). The majority of the RIL produce more kernels/spike than ND 705 indicating transgressive segregation for number of kernels/spike in this population. This demonstrates the possibility of selecting genotypes with higher number of kernels/spike. However, the yield components must be balanced to reach higher levels of grain yield. The top grain yield RIL in the group with the largest values for number of kernels/spike was RIL 30. All the checks and top grain yield RIL were grouped in the intermediate group while the poor grain yield RIL and PI 414566 were among the bottom group except for RIL 96 which was among the intermediate group for the number of kernels/spike. The number of kernels/spike was also positively correlated with grain yield in all environments. The correlation coefficient values for Carrington 2009 and 2010, and Prosper 2009 were pooled and was 0.24, while at Prosper 2010 was 0.57 (Table 8). Previous studies (Waddington et

al., 1986; Donmez et al., 2001; and Underdahl et al., 2008b) also found that increased number of kernels/spike was positively correlated with increased grain yield.

### **Number of spikes/m<sup>2</sup>**

Number of spikes/m<sup>2</sup> averaged 572 spikes overall environments. ND 705, PI 414566, RIL, and checks averaged overall environments 652, 285, 569, and 682 spikes/m<sup>2</sup>, respectively. The range among RIL was from 449 to 709 spikes/m<sup>2</sup> indicating transgressive segregation for the number of spikes/m<sup>2</sup> in this population (Table 6). All the checks and RIL 88 and 30 were among the group with the significantly largest values of number of spikes/m<sup>2</sup>. Line 143 is located in the intermediate group for this trait along with low yielding lines such as 127 and 34. The other low grain yield performance lines (106, 96, and 87) and PI 414566 were among the group with the lowest values for number of spikes per m<sup>2</sup>. There was a significant correlation between number of spikes/m<sup>2</sup> and grain yield. Correlation coefficient values between number of spikes/m<sup>2</sup> and grain yield were pooled for all the environments ( $r=0.43$ ) (Table 8). Our finding concurred with those by Donmez et al. (2001) who found that spike density was also positively correlated with grain yield. However, Underdahl et al. (2008b) did not find a significant association between these two traits.

### **Plant height**

The overall mean of plant height for the genotypes included in this study was 91 cm while, this mean was 97, 71, 91, and 86 cm for ND 705, PI 414566, the RIL, and checks, respectively. Even with the large range among RIL (from 64 to 107 cm) (Table 6), no significant correlation was found between plant height and grain yield in this study (Table 9). Similarly, Underdahl et al. (2008b) and Tsilo et al. (2010) did not find significant

correlation between plant height and grain yield. However, a negative correlation between these two traits has been reported (Cox et al., 1988; Donmez et al., 2001) while another study (McCartney et al., 2005) has reported a positive correlation between plant height and grain yield. The lack of correlation between plant height and grain yield in our study may be due to the narrow genetic variability among the RIL for this trait. In this study, plant height had significant and positive correlation with days to heading at Carrington 2009 and 2010, and Prosper 2009 ( $r=0.30$ ), maturity at Prosper 2009 and Carrington 2010 ( $r=0.42$ ) and correlated with spike color ( $r=-0.26$ ) (Table 9). The negative correlation between plant height and spike color indicates that, in general, the genotypes with white spikes are taller than the genotypes with red dark spikes.

#### **Days to heading and maturity**

The overall mean for days to heading was 56 days and the overall mean of parents ND 705 and PI 414566, RIL, and checks were 55, 76, 55, and 55 days, respectively. The facultative grown habit of PI 414566 explains the long period required by this genotype to flower. The range of RIL was from 49 to 65 days (Table 6) indicating transgressive segregation toward the early types (earlier than ND 705) in this population. No RIL with more days to heading than PI 414566 was recorded. This demonstrates the possibility of selecting genotypes with fewer days to flower than the early parent ND 705. The top three RIL for grain yield (143, 88, and 30) and the checks were among the group with intermediate number of days to heading. RIL 127, 106, and 96 needed more days to flower (65, 62, and 58 days, respectively) than the overall average indicating they may carry the same alleles for this trait as their parent PI 414566.

Table 9. Correlation coefficients (r) among the agronomic traits and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The homogenous r values were pooled and denoted in the table

|                 | Environment | Days to heading     | Spike color          | Maturity            | Grain yield          |
|-----------------|-------------|---------------------|----------------------|---------------------|----------------------|

\* and \*\* Significant at the 0.05 and 0.01 probability levels, respectively.

- Traits were not collected at these locations.

<sup>a</sup> Pooled correlation coefficients across environments.

The overall mean of number of days to maturity was 92 while the two parents ND 705 and PI 414566, the RIL, and the checks matured in 91, 105, 92, and 91 days, respectively. The range for the RIL was from 83 to 103 days (Table 6) indicating transgressive segregation for this trait. Even with the use of the parent PI 414566, a facultative type, the RIL population had 66 lines maturing earlier than the parent ND 705. This provides the possibility of selecting genotypes with earlier maturity than ND 705. As expected, the results for maturity were very similar to the results of days to heading. The correlations between these two traits were 0.61, 0.91, and 0.83 at Carrington 2010, and Prosper 2009 and 2010, respectively. The correlations between these two traits with grain

yield were significantly negative and higher at Prosper compared to those obtained at Carrington (Table 9). This could be due to the late planting at Prosper compared to Carrington in both years. At Carrington, the genotypes had more time to complete the entire cycle and cooler temperatures during the vegetative phase, whereas at Prosper, some genotypes did not have enough time to fully complete their cycle or the temperatures were high during the vegetative phase triggering the early flowering, consequently decreasing the grain yield. This also could be the reason for the negative correlation between these two traits (days to heading and maturity) and spike color at Prosper (Table 9). The late genotypes could not have enough time to express the dark color of the spikes due to the short agriculture season at Prosper. Recent study by Donmez et al. (2001) also found a negative correlation between days to heading and grain yield. However, other studies did not find any significant correlation between number of days to heading and grain yield (Underdahl et al., 2008b; Tsilo et al., 2010) and between days to maturity and grain yield (McCartney et al., 2005).

### **Spike color**

This trait was collected only in the 2010 environments after we observed that in 2009, lines with the red spike color tend to have low grain yield. On a scale from 1 (white) to 5 (dark red), the overall mean for spike color was 3.1 (yellow color). The RIL parents ND 705 had a white color (1.5) while PI 414566 had a red color (4.5). The RIL spike color ranged between the two parents (from 1.4 to 4.5). The overall mean of the checks for spike color was 2 (Table 6). The 2010 data showed a negative and significant correlation between spike color and grain yield (-0.39) (Table 9) confirming our observation in 2009. Zeven (1983) made a review about spike color of bread wheat and found that most results

indicate one (semi)dominant gene conditioning red spike (*Rg*) and appears to be located on chromosome 1BS. However, Khlestkina et al. (2009) found that the genes *Rg-A1* and *Rg-D1* located at chromosomes 1A and 1D, respectively, also encode for spike color. According to the results in this study, some of the spike color genes may be linked to some grain yield genes.

## **Quality traits**

### **Grain protein content**

The mean for grain protein content (GPC) across the four environments was 14.9 % which was also equal to the RIL population mean. ND 705 and PI 414566 parental GPC means were 15.6, and 15.1 %, respectively. The range of the RIL for GPC was from 13.2 to 17.7 %. The overall mean of the checks for GPC was 15.3 % (Table 6). Although the RIL mean for GPC was lower than both parents, several RIL had higher GPC than both parents ND 705 and PI 414566. Besides the cultivar Glenn at Carrington in 2009, the checks were not among the top 10 genotypes for GPC across environments (Table 10). Overall, the parents had similar results for GPC. However, transgressive segregation among the RIL was observed in both directions. Overall environments, the RIL that had significant superior GPC were RIL 10, 4, 40, 90, and 130. These RIL were consistent across all environments being among the 10 highest GPC genotypes in all the environments. For the low GPC group, the RIL were inconsistent. The genotypes with the lowest values of GPC overall environments were not consistent and not always included among the 10 lowest GPC genotypes (Table 10). In general, Prosper in 2010 had the highest values for GPC because it suffered from a strong hail storm and wind decreasing significantly the grain yield. These environmental conditions, unfavorable to high grain yield usually cause a shift

Table 10. Grain protein content and least square difference (LSD) of the top and bottom ten genotypes across all environments (Carrington and Prosper 2009 and 2010). Data were expressed on a 12 percent basis

<sup>a</sup> GPC=grain protein content, %

in nitrogen allocation, increasing the GPC instead of wheat grain yield. Guttieri et al. (2000) and Underdahl et al. (2008a) also found that GPC increased under stress conditions. The GPC, a complex trait, is known to be influenced by environmental conditions such as temperature, soil fertility, and rainfall (Daniel and Triboi, 2000).

GPC had in general no significant association with kernel volume weight except at Carrington in 2010 (0.38) (Table 11). Similarly, Tsilo et al. (2010) reported no significant association between these two traits. GPC was also not associated with kernel hardness except at Carrington 2009 environment (-0.43) (Table 11). Recent study by Kerfal et al. (2010) also did not find significant association between these two traits while Nelson et al. (2006) found positive correlation between them. Negative association was found between GPC and flour extraction (0.24) (Table 11), contrary to Underdahl et al. (2008a) that found no association between these two traits. Hence, further studies may be needed to clarify the relationship between GPC and the other quality traits.

### **Kernel volume weight**

Across locations, the mean for kernel volume weight (KVV) was  $749 \text{ kg m}^{-3}$  while the overall means of ND 705, PI 414566, RIL, and checks were 791, 598, 749, and  $774 \text{ kg m}^{-3}$ , respectively. The RIL range for KVV was from 669 to  $790 \text{ kg m}^{-3}$  (Table 6). The check Glenn was constantly the top genotype for KVV as was previously reported by Mergoum et al. (2006) (Table 12). Carrington 2009 had the highest values for KVV followed by Carrington 2010 environment (Table 6). Carrington environments had better climate conditions favoring this quality indicator trait. Based on KVV overall means, the top 10 genotypes for KVV were three checks (Glenn, Barlow, and Steele-ND), six RIL (47, 149, 30, 124, 167, and 47), and one the parent ND 705. While, the bottom group with

the lowest values of K VW comprised the rest of RIL plus the non-adapted parent, PI 414566 (Table 12). Glenn, ND 705, and the RIL 47 K VW were very consistent across environments. In general, K VW has a higher heritability compared to grain yield (Patil et al., 1994; Tsilo et al., 2010) being more constant across environments.

Table 11. Correlation coefficients (r) among the quality traits and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The homogenous r values were pooled and denoted in the table

|          | Environment | Grain protein content | Kernel hardness   | Flour extraction     |
|----------|-------------|-----------------------|-------------------|----------------------|

\*\* Significant at the 0.01 probability level.

<sup>a</sup> Pooled correlation coefficients across environments.

For this trait, transgressive segregation was not observed. The adapted ND 705 parent had the highest value in this study, excluding the check Glenn, while the non-adapted PI 414566 parent had the lowest value for K VW (Table 12). The higher susceptibility for diseases overall of the non adapted parent PI 414566 compared to the adapted parent ND 705 could be a factor, among several others, influencing the large K VW range between these two parents. Also, the disease resistant genes could influence the K VW performance of the RIL population.

Table 12. Kernel volume weight and least square difference (LSD) of the top and bottom ten genotypes across all environments (Carrington and Prosper in 2009 and 2010)

<sup>a</sup> KVW=kernel volume weight, kg m<sup>-3</sup>.

KVW was not associated with kernel hardness and was positively related with flour extraction in this study (0.30) (Table 11). Previous investigations (Lee et al., 2006) found positive correlation between these KVW and kernel hardness. Similarly, several authors (Ohm et al., 1998; Lyford et al., 2005; Lee et al., 2006) reported a positive correlation between KVW and flour extraction. KVW is known to be correlated with wheat quality (Bergman et al., 2000; Aguirre et al., 2002) and is commonly believed in the wheat market as a valuable trait to enhance flour extraction. Normally, genotypes with greater values of KVW are believed to have more dense kernels with the potential of more endosperm per unit of kernel that will yield in higher flour. KVW has been used in many countries as an indicator of overall grain quality and an important factor to determine wheat prices. However, some authors (Schuler et al., 1995; Bergman et al., 2000) did not find any association between KVW and flour extraction. Lyford et al. (2005) mentioned that two genotypes can “pack” differently due to physical characteristics, affecting KVW values, but having similar flour extraction percentages. Similarly, in ND, the check Glenn, the most grown cultivar in the USA wheat spring region since 2007, has a very high KVW (Mergoum et al., 2006) but average flour extraction (Dr. M. Mergoum, personal communication).

### **Kernel hardness**

Kernel hardness is an important index for differentiation of wheat classes. In this work, the overall mean for kernel hardness was 70 (hard texture). The means of ND 705, PI 414566, RIL, and checks were 76 (hard), 63 (medium hard), 70 (hard), and 77 (hard) respectively. The range of RIL was from 57 (medium hard) to 86 (very hard) (Table 6). This RIL population developed from a medium hard (PI 414566) and a hard (ND 705)

parent, no soft or extra hard texture RIL were found. Based on the overall mean, the top 10 hard genotypes were seven RIL (119, 6, 138, 54, 39, 104, and 19) and three checks (Barlow, Alsen, and Glenn). However, only the RIL 119 and 6, and Barlow were significantly harder compared to the other genotypes. The bottom group of 10 genotypes with the lowest values of kernel hardness included only RIL (Table 13).

The correlation between kernel hardness and flour extraction across all environments was 0.39 (Table 11). This result was in agreement with Ohm et al. (1998) and Nelson et al. (2006) who reported a positive association between these two traits. Increased kernel hardness requires higher milling energy, but based on our results and previous finding (Symes, 1965; Bassett et al., 1989), harder kernels had higher flour yield. Pomeranz and Williams (1990) did further studies and found that higher values of kernel hardness generate better flowing and sifting properties during milling. The main effect of hardness on bread-making qualities is attributed to higher starch damage during milling. This damage increases both water absorption and hydrolysis of starch into fermentable sugars that contribute to loaf volume (Pomeranz and Williams, 1990). However, Lyford et al. (2005) found negative association between these two traits. Their explanation for the negative correlation was due to the fact that working with hard wheat population, softer kernels will generate higher flour extraction rates.

### **Flour extraction**

Flour extraction represents an important economic variable to millers. The overall mean for flour extraction across the four environments was 61 % while the means of ND705, PI 414566, RIL, and the checks were 66, 54, 61, and 63 %, respectively. The flour

50

<sup>a</sup> KH=kernel hardness is a category classification according to the hardness index (HI) shown in the material and methods section.

extraction of the RIL ranged from 46 to 67%. In general, the genotypes had better flour extraction at Carrington than at Prosper (Table 6).

The parent ND 705 was part of the top 10 genotypes with the highest values of flour extraction. This was probably the main reason why several RIL such as 82 and 141 had high flour extraction, slightly better even than the best check (Faller) and better than the adapted parent ND 705 (Table 14). Flour extraction is related to several factors such as disease resistance. The incorporation of disease resistance in the genotypes will reduce the occurrence of shriveled grain; consequently, flour extraction yield will increase (Cox et al., 1989). ND 705 had satisfactory disease resistance overall. Probably, the RIL 82 and 141 incorporated these resistant genes from ND 705 because PI 414566 was highly susceptible for diseases overall. The non-adapted parent was located among the 10 genotypes with the lowest values for flour extraction along with nine RIL (Table 14).

#### **Associations among agronomic and quality traits**

Grain yield was significantly associated with kernel volume weight. The correlations at Carrington 2009 and 2010, and at Prosper 2009 were pooled (0.49). At Prosper 2010, the correlation between these two traits was highly significant (0.78). It is worth to notice that the correlation was higher in the environment under the highest stress conditions (Prosper 2010) (Table 15). Guttieri et al. (2001) found in their study that drought-sensitive genotypes had a significant reduction in grain yield and also KVV. However, the superior genotypes for grain yield were also the superior genotypes for KVV under drought conditions confirming our results. The same study concluded that the genotypes with stable grain yield under stress conditions were also the genotypes with stable KVV. Other studies (McCartney et al., 2005; Lee et al., 2006) also found positive

<sup>a</sup> FE=flour extraction, %.

and significant association between these two traits under regular field conditions. However, Tsilo et al. (2010) did not detect significant correlation between grain yield and KVW. Guttieri et al. (2001), McCartney et al. (2005), and Lee et al. (2006) worked with released cultivars, double haploid population developed from two adapted parents, and blended samples from two adapted cultivars, respectively, and they identified positive correlation between these traits. This work showed that with the use of a non-adapted parent, this population had also significant association between these two important traits.

Grain yield was significantly correlated with GPC only at Carrington in 2010 (0.18) (Table 15). Usually, these two traits are known to have negative relationship due to temperature and nitrogen shifts allocating the nitrogen to one or to the other trait (Daniel and Triboi, 2000). Groos et al. (2003) also reported a negative and significant association between these two traits. However, these authors concluded that there was no strong negative pleiotropic effect detected between these two traits, suggesting that both traits can be improved using the same breeding scheme. Other studies (Underdahl et al., 2008a) also did not find negative and significant correlation between grain yield and GPC confirming our findings.

Our results show that grain yield and flour extraction had positive and significant correlations. These correlations across environments were homogeneous and, consequently, pooled together (0.22). Lee et al. (2006) found also a positive and significant correlation between grain yield and flour extraction. These traits represent the most important economic variable to farmers and millers, respectively. The main goal of wheat breeding is to develop cultivars with higher attributes for both traits.

Table 15. Correlation coefficients (r) among the agronomic and quality traits, and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The r values for single environment are denoted in the table

\* and \*\* Significant at the 0.05 and 0.01 probability levels, respectively.

- No lodging at this location.

--- Traits were not collected at these locations.

<sup>a</sup> Correlation coefficients for a single environment.

The 1000-kernel weight was positively associated with KVW and flour extraction across all the environments (Table 15). That indicates why 1000-kernel weight was used to predict flour extraction by Lyford et al. (2005). McCartney et al. (2005) reported also a significant and positive correlation between these two traits. According to these results, 1000-kernel weight seems to be the yield component that has the greatest influence on KVW and flour extraction, indicating that the heavier kernels are related to higher values for these two quality traits. However, Bergman et al. (2000) did not find any association between 1000-kernel weight and KVW, and flour extraction. They concluded that 1000-kernel weight cannot be used to predict these two quality traits.

Days to heading and maturity were significantly and negatively correlated with KVW. Days to heading also had a negative association with flour extraction (Table 15). Similarly, Tsilo et al. (2010) reported a significant negative correlation between these two traits confirming our findings. These results might suggest that late heading genotypes apparently had lower grain filling rates than early genotypes; consequently, they had lower values of KVW giving the short grain filling period known in the USA spring wheat region. The late heading genotypes might have the genes for late heading and maturity coming from PI 414566 as well as the genes for low KVW. However, McCartney et al. (2005) found a significant positive correlation between these two traits indicating that the late samples had better KVW than the early plants. This result can be adhered in most environments that have long grain filling period.

The highest negative correlation between lodging and KVW was reported at Prosper in 2010 (0.66) (Table 15). This high correlation at this environment is due to the unfavorable conditions that increased the percentage of lodging at this location;

consequently, affecting significantly the KVV for the genotypes that are susceptible to lodging. Contrary to our findings, McCartney et al. (2005) found a positive relationship between these two traits.

Spike color was negatively associated with KVV (0.35) (Table 15). This indicates that the RIL with darker colored spikes, with the red colored spike genes coming from the non-adapted parent PI 414566, may carry genes for low KVV or some of the spike color genes may be linked to KVV genes.

## CONCLUSIONS

The adapted (ND 705) and non-adapted parent (PI 414566) showed drastic differences for all the agronomic and quality traits studied. Consequently, the RIL showed significant variances for these traits. Transgressive segregation occurred for all the agronomic and quality traits except for spike color and K VW, suggesting possible traits improvement using these types of mating.

Overall, the genotypes had better performance for agronomic traits, kernel volume weight, and flour extraction in Carrington compared to Prosper due to favorable environment conditions at Carrington during these two years. Within locations, except for flour extraction that had similar results at Carrington 2009 and 2010, these traits had higher levels in 2009 than 2010.

The checks Faller, Barlow, and Steele-ND along with the RIL 143 and 88 had significant superior grain yield across environments. The RIL 143 and 88 showed relatively low rates of lodging and kernel shattering and overall good agronomic attributes, demonstrating high potential to be included in the HRSW breeding program. Also, the RIL 47 had superior attributes for K VW, and RIL 82 and 141 had superior attributes for flour extraction. These RIL can be valuable for the HRSW breeding program.

Grain yield along with GPC, K VW, and flour extraction are the most important traits for farmers and millers to remain competitive. These four traits are complex and influenced by many factors and will continue to be a major challenge for wheat breeders, farmers, and millers. The use of elite x elite crosses continues to be the most common and effective type of cross to develop new cultivars in breeding programs. However, with the concern that narrow germplasm may restrict breeding flexibility and slow genetic progress

to biotic and abiotic stresses tolerance, it seems that the development of populations originated from adapted x non-adapted germplasm is a common practice by breeders to broaden the genetic variability of their germplasm and consequently increase genetic gain. This study has showed clearly the value of using non-adapted sources of germplasm to broaden the germplasm and to improve several wheat economic traits.

- Traits were not collected at these locations.

**PAPER 2. VARIATION OF WHEAT KERNEL CHARACTERISTICS AND  
ASSOCIATIONS WITH AGRONOMIC AND QUALITY TRAITS**

## ABSTRACT

Wheat kernel is the main component of wheat grain yield and an important factor for milling characteristics. Focusing on wheat kernel characteristics might be a key element to improve wheat genotypes for agronomic and quality traits. A study conducted at Carrington and Prosper, North Dakota during 2009 and 2010 evaluated the associations among kernel traits including kernel length, width, length/width ratio, weight and area, and agronomic and quality traits. A population of 160 Recombinant Inbred Lines (RIL) developed between two contrasting genotypes (ND 705 and PI 414566) was used to study these associations. The results showed that kernel traits had high correlation among them and they exhibited a normal distribution suggesting a polygenic inheritance. Grain yield, kernel volume weight, and flour extraction were highly correlated with kernel width, length/width ratio, weight, and area. Results from this study indicate that kernel traits can play a significant role in improving agronomic and quality traits. Higher values for grain yield, kernel volume weight, and flour extraction were significantly associated with spheroid or round shape (short and plump), large, and heavy kernels. Based on this study, breeders should pay attention to kernel traits during the parental selection for the development of populations with improved agronomic and quality attributes.

## INTRODUCTION

Wheat kernel is the main component of wheat grain yield. Also, it has been reported by researchers (Campbell et al., 1999; Wiersma et al., 2001; Dholakia et al., 2003; Breseghello and Sorrells, 2007; Sun et al., 2009) that kernel traits including kernel weight and size are important for milling characteristics. The focus on wheat kernel characteristics might be a key point in the selection process for the improvement of wheat; therefore, increasing the possibility of success in the breeding program. However, wheat kernel traits are generally complex and believed to be of quantitative nature of inheritance. In addition, wheat kernel characteristics are frequently influenced by environment, having high genotype x environment interaction (Campbell et al., 1999; Sun et al., 2009). Likewise, most of the wheat quality traits are under complex genetic and environmental control (Nelson et al., 2006; Dornez et al., 2008).

Kernel characteristics, such as kernel length, width, shape, area, and weight are very important, as they are highly related to wheat quality traits. However, these traits are in general not well investigated. Kernel weight can be affected by kernel length and width (Campbell et al., 1999; Dholakia et al., 2003) and based on some studies (Wiersma et al., 2001), it enhances flour yield. Larger kernels were reported to increase flour extraction values (Marshall et al., 1986; Chastain et al., 1995). Similarly, kernel shape affects kernel volume weight (KVW) (Campbell et al., 1999). Also, in a geometrical model study, changes in kernel shape and size were able to enhance flour extraction up to 4.7% (Marshall et al., 1984). High values of flour yield can also be achieved by increased kernel hardness (Symes, 1965; Bassett et al., 1989).

In recent years, scientists (Dholakia et al., 2003; Breseghello and Sorrells, 2007; Sun et al., 2009) have focused on traits to be used as markers for indirect selection to improve wheat quality attributes. Dholakia et al. (2003) and Sun et al. (2009) found similar associations among the kernels characteristics working with two different Recombinant Inbred Lines (RIL) populations. Dholakia et al. (2003) developed a 106 RIL population by crossing two hexaploid wheat cultivars PH 132 and WL 711. In this study, kernel weight showed a significant correlation with kernel length and width (0.51, 0.68, respectively). Kernel length and width were also significant correlated (0.57). Similarly, Sun et al. (2009) worked with a set of 131 RIL population developed from the cross between two Chinese lines (Chuan 35050 x Shannong 483). They also reported that kernel weight had significant correlation with kernel length and width (0.42, and 0.75, respectively) and kernel length and width were also significant correlated (0.22). In addition, Sun et al. (2009) compared the association between K VW with the kernel traits. They found a significant positive association of K VW and kernel weight (0.19), negative correlation with kernel length (0.22), and no significant relationship with kernel width.

Lee et al. (2006) used two hard white wheats, 'Betty' and 'Trego', which were combined at different percentages and average values from the blended percentages and locations were associated. Kernel width had significant positive correlation with flour extraction and K VW (0.50, and 0.28, respectively). This finding was not in agreement with Sun et al. (2009) that did not find any correlation between K VW and kernel width. However, kernel weight was positively associated with flour extraction and K VW (0.74, and 0.56, respectively) which was in agreement with Sun et al. (2009) findings. Kernel weight and width were also strongly correlated (0.83). Lee et al. (2006) reported positive

association between KVW and flour extraction (0.44). A research by Breseghello and Sorrells (2006) using 95 selected soft winter wheat cultivars released by 35 different seed companies or research institutions in the last 30 years studied the associations between kernel traits (kernel length, width, weight, and area) and quality traits such as flour extraction. Contrary to Lee et al. (2006), they did not find significant correlations between kernel traits and flour extraction, except between flour extraction and kernel weight at only one location (0.23).

Breseghello and Sorrells (2007) used two different RIL populations, SxO and RxG. SxO population derived from a cross between the synthetic hexaploid wheat W7984 and the spring wheat cultivar 'Opata 85'. RxG population developed from the cross between a soft white spring wheat cultivar 'AC Reed', and a hard red spring wheat (HRSW) cultivar 'Grandin'. The dimensions of the kernels were determined based on two photos of 20 kernels placed in orthogonal directions symbolizing each RIL. They found strong correlations among the kernel traits: kernel length and kernel area (0.90 and 0.84 in SxO and RxG populations, respectively); kernel length and kernel volume (0.78 and 0.67); kernel length and kernel weight (0.80 and 0.68); kernel width and kernel area (0.84 and 0.58); kernel width and kernel volume (0.68 and 0.69); and kernel width and kernel weight (0.68 and 0.67). However, the correlation between kernel length and kernel width was not as high as previous correlations (0.30 and 0.22). The population SxO showed stronger correlations among the kernel traits than population RxG. Also, there were stronger correlations between kernel length and the other traits (kernel area, volume, and weight) than kernel width and the other traits.

Recently, Tsilo et al. (2010) studied a population of 139 RIL derived from the cross between two HRSW lines MN98550 ('Bacup'/'McVey') and MN99394 (SD3236/SBF0402). The results from this study showed a strong correlation between kernel traits and KVV confirming previously reported results by Sun et al. (2009). KVV was also significantly associated with kernel width and weight (0.35, 0.29, respectively).

Several studies conducted on the kernel characteristics showed the potential role of these traits in the wheat quality. However, several other studies have reported conflicting results. Therefore, this study was designed to (1) examine the kernel characteristics variations derived from an elite x non-adapted parents, (2) the kernel characteristics associations with agronomic and quality traits to explore their potential uses in breeding programs, in order to develop new superior cultivars.

## MATERIAL AND METHODS

### Material

This study was conducted using a population of 160 RIL. This population was developed from a cross between ND 705 and PI 414566. The ND 705 is a HRSW line developed by the HRSW breeding program at North Dakota State University (NDSU). The PI 414566 is originally from China and it was obtained from the USDA National Small Grains Collection. It is described as a facultative type of wheat which requires cold temperature to flower, tall, brown kernels, and susceptible for diseases such as stripe rust caused by *Puccinia striiformis*. The RIL population was advanced through single seed descent method to F<sub>8</sub> generation and it was obtained from the Wheat Germplasm Enhancement program at NDSU. A combination of field nurseries at New Zealand, North Dakota, and greenhouse were used to advance this population. The selection of the parents used to develop this RIL population was based on the genetic divergence between the parents in order to produce a RIL population with significant polymorphism for kernel, agronomic, and quality traits. The number of RIL used in this study was determined by the amount of seeds available of each RIL.

The checks used in this study were: 'Alsen' (PI 615543) (Frohberg et al., 2006), 'Steele-ND' (PI 634981) (Mergoum et al., 2005), 'Glenn' (PI 639273) (Mergoum et al., 2006), 'Faller' (PI 648350) (Mergoum et al., 2008), 'Barlow' (PI 658018) (Mergoum et al., 2011), 'Briggs' (PI 632970) (Devkota et al., 2007), and 'Alpine'. All the check cultivars are HRSW varieties except Alpine which is a hard white spring wheat variety.

## **Field experiment**

The RIL, their parents (ND 705 and PI 414566), and checks (Alsen, Steele-ND, Glenn, Faller, Barlow, Briggs, and Alpine) were evaluated in the summers of 2009 and 2010 at two field locations in ND; Carrington Research Extension Center near Carrington and Prosper Research Plots near Prosper. These sites represent two diverse environments. Carrington is located in the Central ND region with an altitude of 484 m. The soil type at Carrington is Heimdal-Emrick series (loamy, mixed, superactive, Calcic/Hapludolls). Prosper is located in the Red River Valley region (Eastern ND) with an altitude of 274 m. The soil type at Prosper is Bearden series (fine silty, mixed, superactive, frigid Aeric Calciaquolls) (USDA-NRCS, 2011).

In 2009, the planting dates were May 7 at Carrington, and May 28 at Prosper. The harvesting dates were August 26 at Carrington for all the lines except the parent PI 414566 which was harvested on October 6. At Prosper all the lines were harvested on September 18 except PI 414566 which was harvested on October 13. The winter of 2008-2009 had a high amount of snow causing field flood delaying the planting date. Consequently, PI 414566 as a facultative type requiring a longer period to complete its cycle did not have enough cold temperature to completely flowering. In 2010, the planting dates were April 21 at Carrington, and May 20 at Prosper. The harvesting dates were August 18 and 27 at Carrington and Prosper, respectively. PI 414566 was vernalized for three weeks prior to planting at Prosper. However, the emergence rate of the PI 414566 vernalized seeds was very low because of the poor and heavy soil characteristics at Prosper in 2010. Carrington was planted earlier; consequently, PI 414566 had enough cold temperature to flower,

therefore completing its cycle successfully. Sowing rates was  $113 \text{ kg ha}^{-1}$  in all environments.

In 2009, the experiments included the  $F_{8,9}$  RIL, their parents, and checks. In fall 2009, the RIL were sent to New Zealand winter nursery for seed increase. Consequently, in 2010, the experiments included the  $F_{10:11}$  RIL, their parents, and checks. The entries were arranged in a  $13 \times 13$  partially balanced square lattice design, with two replicates. The experimental units consisted of seven rows, 2.44 m long and 12.7 cm apart.

### **Data collection**

The grains from harvested plots were cleaned by using a clipper grain cleaner before measuring the following traits.

#### **Agronomic traits**

- Grain yield ( $\text{kg ha}^{-1}$ ) – determined by weighing the cleaned grain harvested from each plot.
- Yield components:
  - ✓ Number of spikes ( $\text{spikes m}^{-2}$ ) – determined by counting the number of spikes in two 61 cm long rows per plot. Counts were then converted to determine total number of spikes per square meter.
  - ✓ Number of kernels ( $\text{kernels spike}^{-1}$ ) – calculated by averaging the kernels from ten individual spikes selected at random from each plot. The kernels were counted by the electronic seed counter (Seedburo Equipment Co., Chicago, IL) after threshing the spikes.
  - ✓ 1000-kernel weight (g) determined by ‘Digital Image Analysis’ (DIA) – calculated based on the number of kernels within 10 g samples from each

plot used in the DIA. The results were converted and the weight of 1000 kernels was determined (Doehlert et al., 2004).

- Plant height (cm) – measured from the soil surface to the top of the spike, excluding the awns at maturity. An average plant height was recorded from each plot.
- Days to heading (days) – recorded when inflorescences fully emerged in at least 50% of the spikes and was calculated as the number of days from planting to heading.
- Lodging (%) – estimated by the percent of lodged plants per plot when lodging occurred at a given environment.
- Maturity (days) – recorded when kernels fully complete the physiologic maturity in at least 50 % of the spikes. It was calculated as the number of days from planting to maturity.
- Emergence (%) – estimated by the percent of fully emerged plants per plot.
- Spike color (1-5) – visually rated by using a scale having equidistant values from 1 (white) to 5 (dark red).

### **Quality traits**

- Grain protein content (%) – measured according to American Association of Cereal Chemists (AACC) standard method 46-30 (AACC International, 2000), using an Infratec 1226 Cold Grain Analyzer expressed on a 12 percent basis.
- Kernel volume weight ( $\text{kg m}^{-3}$ ) – measured according to AACC standard method 55-10 (AACC International, 2000).

- Kernel hardness (0-90+) – measured using the single kernel characterization system (SKCS) 4100 instrument (Perten Instruments, Springfield, IL). This instrument measured the force needed to crush the kernels which is expressed as a hardness index. Table 1 has the kernel hardness category classification according to the hardness index.

Table 1. Kernel hardness category classification according to the hardness index (HI)

| Category    | HI <sup>a</sup> |
|-------------|-----------------|
| Extra hard  | 90 +            |
| Very hard   | 81 – 90         |
| Hard        | 65 – 80         |
| Medium hard | 45 – 64         |
| Medium soft | 35 – 44         |
| Soft        | 25 – 34         |
| Very soft   | 10 – 24         |
| Extra soft  | Up to 10        |

<sup>a</sup> HI=hardness index

- Flour extraction (%) – 150 g cleaned wheat samples were tempered to 16.0 % moisture for 16 hr before being milled on a Brabender Quadrumat Junior Mill according to standard procedure used at the Department of Cereal and Food Sciences at North Dakota State University. The flour extraction percentage was calculated by dividing the flour weight of straight grade flour over the total grain weight milled (150 g).

#### **Kernel traits**

- Kernel length (mm) – determined by the DIA. Ten-gram samples were placed on a backlit glass platform within a predefined field of view. An analog camera was mounted at one meter height from the platform. Kernels were manually positioned on the platform ensuring they were not touching each other and a

photograph was taken. The images were processed in a computer program called 'Aphelion' (Amerinex Applied Imaging, Amherst, MA) to determine the kernels major and minor axes. The major axes represented the kernel length. Means were calculated from 10 g samples for each plot (Doehlert et al., 2004).

- Kernel width (mm) – determined by the DIA. In the same manner as kernel length except that in this case the minor axes determined by Aphelion program represented the kernel width. This was determined by the means of kernels in 10 g samples from each plot (Doehlert et al., 2004).
- Kernel length / width by DIA ratio – calculated by dividing the kernel length mean by the kernel width mean for each plot.
- Kernel weight (g) determined by 'Digital Image Analysis' (DIA) – calculated based on the number of kernels within 10 g samples from each plot used in the DIA. The results were converted and the weight of 1000 kernels was determined (Doehlert et al., 2004).
- Kernel area (mm<sup>2</sup>) – determined by the DIA. Using the same procedure as kernel length and width. The Aphelion program determined the image area which was the kernel area. A 10 g samples from each plot was used to determine the kernel area (Doehlert et al., 2004).
- Kernel width (mm) – measured using Single Kernel Characterization System (SKCS) 4100 instrument (Perten Instruments, Springfield, IL). Kernel width is measured as the size of the gap formed between the crescent and the rotor at the engagement of the seed.

- 1000-kernel weight (g) – measured using the SKCS 4100 instrument (Perten Instruments, Springfield, IL). Kernel weight is measured as the electrical force required to return the boat into which the individual seeds are dropped to its original horizontal position. This force is proportional to the mass of the seed. The instrument provides kernel weight based on 1000-kernel weight.

### Data analysis

Data were subjected to the analyses of variance (ANOVA), using the MIXED procedure of the Statistical Analyses System (SAS Institute, 2004). Within the mixed model, the RIL, their parents, and checks were considered fixed effects. Environments and blocks were considered random effects. The ANOVA was conducted within and across environments. Environments were considered homogeneous when the ratio of the effective error variances for each trait was less than 10-fold (Appendix Table 1) (Hartley, 1950; Patterson and Silvey, 1980; Geng et al., 1982; Mitchell, 1995). Data were subjected to combined analysis if environments were homogeneous. Tables 2 and 3 show the pertinent sources of variation, degrees of freedom, and the appropriate expected mean squares.

Table 2. Single analyses of variance for a lattice design, with treatment as fixed effects, and rep as random effects

| SOV               | DF <sup>a</sup>       | MEAN SQUARE |                                      | F-test    |
|-------------------|-----------------------|-------------|--------------------------------------|-----------|
|                   |                       | Obs         | Expected                             |           |
| Rep               | $r - 1$               | M1          |                                      | non-valid |
| Blocks within rep | $r(k - 1)$            | M2          |                                      | non-valid |
| Treatment         | $(t - 1)$             | M3          | $\sigma^2 + r\sum\alpha_i^2 / (t-1)$ | M3 / M4   |
| Error             | $(k - 1)(rk - k - 1)$ | M4          | $\sigma^2$                           |           |
| Total             | $rk^2 - 1$            |             |                                      |           |

<sup>a</sup> = The letters k, t, and r refer to the size of the lattice, the number of treatments, and the number of replications, respectively.

Mean separation test was performed using an F-protected least significant difference (LSD) value at  $P \leq 0.05$  level of significance for each evaluated trait. Correlations between kernel traits and the different agronomic and quality traits were calculated for single environments using the CORR procedure of SAS (2004). Homogeneity of these correlations was tested, and results were pooled if homogeneous. Otherwise, correlations from single environments were kept. The homogeneity test of the correlations was determined using the  $\chi^2$ .

Table 3. Combined analyses of variance for a lattice design, across two years and two locations, with treatment as fixed effects, and rep and environment (year x location) as random effects

| SOV                    | DF <sup>a</sup>         | MEAN SQUARE |  | F-test    |

| Block within Rep x Env | $er (k - 1)$            | M4          |  | non-valid |
| Env x Treat            | $(e - 1) (t - 1)$       | M5          | $\sigma^2 + r\sigma_{et}^2$                            | M5 / M6   |
| Error                  | $e(k - 1) (rk - k - 1)$ | M6          | $\sigma^2$   |           |
| Total                  | $ert - 1$               |             |  |           |

<sup>a</sup> = The letters k, t, e, and r refer to the size of the lattice, the number of treatments, the number of environments, and the number of replications per environment, respectively.

## RESULTS AND DISCUSSION

### Environment effects and data analysis

The ANOVA for each environment was performed. Error variances were homogeneous for all the traits among the four environments except for lodging. Consequently, a combined analysis across the four environments was performed for all the traits except lodging. Homogeneity test was verified using the 10-fold (Appendix 1).

The analysis of variance summaries for the agronomic, quality and kernel traits are reported in Table 4, while the means of the experiment, parents, RIL, and checks for the combined and single environments are shown in Table 5.

Significant variance was observed among the genotypes for all the agronomic, quality, and kernel traits. Also, environment had a significant effect on all traits. Consequently, a significant treatment x environment interaction occurred for all the traits (Table 4). The agronomic and kernel traits, KVW, and flour extraction levels were higher, in general, at Carrington compared to Prosper. Within each location, except for flour extraction that showed similar results at Carrington 2009 and 2010, these traits levels were also higher in 2009 compared to 2010. Grain protein content (GPC) had the highest values at Prosper in 2010. Prosper environments especially in 2010 went through a strong hail storm and wind significantly decreasing several traits including wheat grain yield, kernel traits values, KVW, and flour extraction. Climatic conditions at Carrington were, in general, more favorable than at Prosper for spring wheat production in both 2009 and 2010. The hardest kernels were obtained at Carrington 2009 (Table 5). The adapted checks (Alsen, Steele-ND, Glenn, Faller, Barlow, Briggs, and Alpine) showed, in general, superior performance compared to the RIL and their parents (Table 5).

Table 4. Source of variation, degrees of freedom, mean square, and level of significant of the agronomic, quality, and kernel traits of the RIL, their parents, and checks grown at Carrington and Prosper, ND, during 2009 and 2010

- Traits were not collected at these locations.

### Agronomic and quality traits

The agronomic and quality data used in this paper are reported in Table 5. However, the analysis and discussion of these data are reported only in paper 1, in order to avoid duplication.

### Kernel traits

Based on previous works cited in the literature review, there are different methods to measure kernel traits (theoretical geometric model, kernel size distribution, manual measurements, single kernel characterization system (SKCS), and digital image analysis (DIA)). In this study, kernel width and kernel weight (represented by 1000-kernel weight in

this work) were measured using both SKCS and DIA. The remaining kernel traits (kernel length and area) were measured by DIA.

The two kernel traits measured by SKCS and DIA were highly correlated. The correlation for kernel weight evaluated by the two methods was 0.93 and for kernel width was 0.85. Although, these two methods showed similar results, SKCS demonstrated problems with samples having small kernel size by either over-estimating their weight or size. SKCS uses 300 kernels samples, but the small kernels included in the sample are usually discarded. PI 414566 for instance, had very small kernels and according to SKCS method, the 1000-kernel weight mean of this parent was 16.0 g while in reality it was 23.3 g using the DIA method. The overall mean of kernel width for PI 414566 was 2.34 and 2.29 mm using SKCS and DIA, respectively. At Prosper, the differences between the values of these two methodologies were even larger because of the small kernel size of PI 414566 at this location (Table 5). Due to the lack of accuracy of the SKCS method, particularly for samples with small kernel size, only data by DIA is reported in this study.

### **Kernel length**

The overall mean for kernel length was 5.72 mm. ND 705, PI 414566, and the RIL means were 5.47, 5.61, and 5.72 mm, respectively. The range of the RIL was from 5.15 to 6.48 mm (Table 5). Kernel length showed a continuous variation, suggesting a polygenic inheritance (Fatokun et al., 1992; Tsilo et al., 2010). Transgressive segregation occurred in both directions (Figure 1). Kernels were longer, in general, in 2009 than in 2010. Specifically at Carrington, kernels were longer than those harvested at Prosper. In 2010 at Carrington, PI 414566 completed its entire grown cycle resulting in a high value for kernel length of 6.02 mm (Table 5).

Kernel length was significantly correlated with all the other kernel traits except kernel width. The correlations between kernel length and length/width ratio, area, and 1000-kernel weight were 0.61, 0.69, and 0.42, respectively (Table 6). These correlations showed that kernel characteristics are inter-related and compensate for each other during the kernel formation and development. In fact, previous studies have also reported similar results. Dholakia et al. (2003), and Sun et al. (2009) found significant correlation between kernel length and 1000-kernel weight while Bergman et al. (2000) and Breseghello and Sorrells (2007) found significant correlation between kernel length and kernel area and weight.

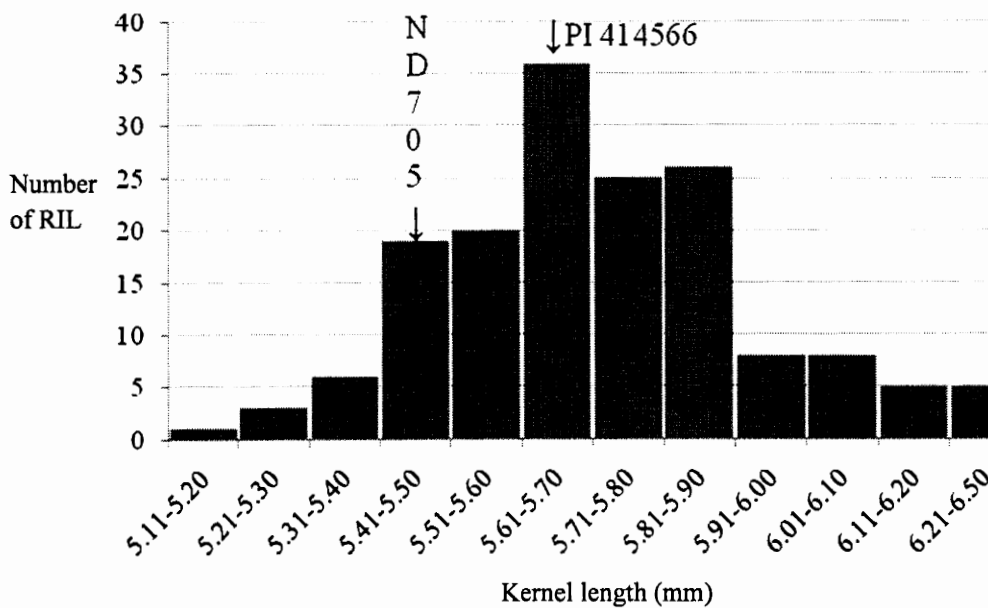

Figure 1. Frequency distribution of 160 RIL and their parents for kernel length means over two locations (Carrington and Prosper), and two years (2009 and 2010) (Parental means are marked with arrows).

### Kernel width

Kernel width averaged 2.74 mm across environments. The means of ND 705, PI 414566, and RIL were 2.84, 2.29, and 2.74 mm, respectively. The range of the RIL for

kernel width was from 2.46 to 2.99 mm (Table 5) showing a positive transgressive segregation with values higher than ND 705 for this trait (Figure 2). Transgressive segregation gives a chance to the breeders to improve this trait. Kernel width had a non-discrete variation; consequently, this trait is influenced by many genes (Fatokun et al., 1992; Tsilo et al., 2010). The RIL and their parents had larger values for kernel width in Carrington than Prosper. Within each location, the kernel width, in general, was superior in 2009 than 2010, except for PI 414566 at Carrington 2010 where this parent fully completes its cycle reaching its normal diameter in this environment (Table 5).

Table 6. Correlation coefficients (r) among the kernel traits and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The r values for single environment are denoted in the table

|                                     | Environment | Kernel width | Kernel length/<br>width ratio | Kernel area | 1000 kernel<br>weight |

\* and \*\* Significant at the 0.05 and 0.01 probability levels, respectively.

<sup>a</sup> Correlation coefficients for a single environment.

Kernel width was significantly correlated with kernel length/width ratio (-0.70) and kernel area (0.80). Similarly, kernel width was also significantly associated with 1000-kernel weight with correlation coefficient values of 0.88 at Carrington 2009 and 2010 and

Prosper 2009; and 0.93 at Prosper 2010 (Table 6). The high correlation among these traits may provide an opportunity for the breeders to select indirectly to improve kernel characteristics. The 1000-kernel weight for instance is used frequently in breeding programs, it is an easy trait to measure, and may be a good trait for indirect selection for kernel width. Our results are in agreement with Bergman et al. (2000), Dholakia et al. (2003), Sun et al. (2009), and Tsilo et al. (2010) who reported high correlation between kernel width and kernel weight. Based on our results and previous studies, kernel width was more indicative than kernel length due to its high correlation with kernel weight (Bergman et al., 2000) and kernel area (Bergman et al., 2000; Sun et al., 2009).

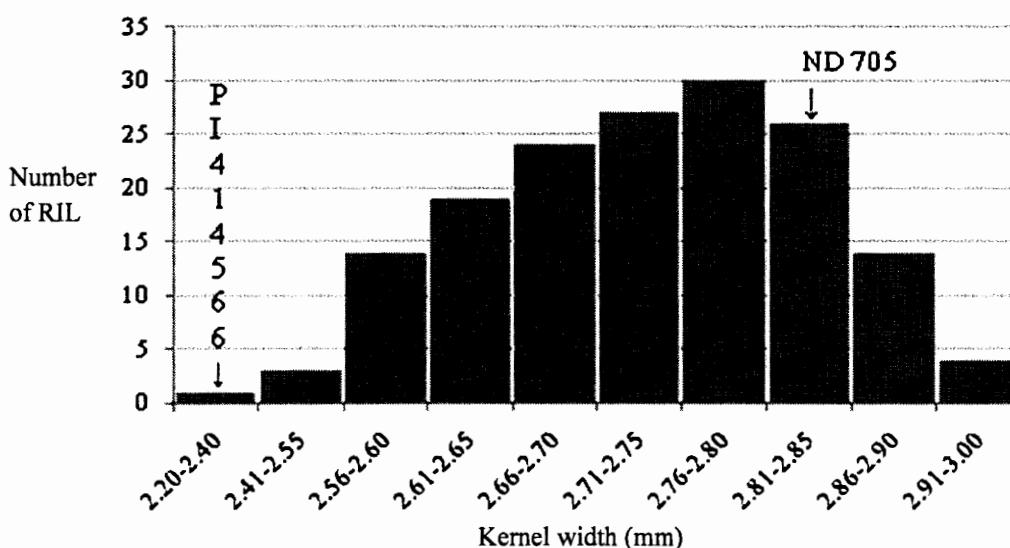

Figure 2. Frequency distribution of 160 RIL and their parents for kernel width means over two locations (Carrington and Prosper), and two years (2009 and 2010) (Parental means are marked with arrows).

### Kernel length/width ratio

This trait describes more the shape of kernel. Across environments, the overall mean for kernel length/width ratio was 2.09. The means of this ratio for ND 705, PI 414566, and RIL were 1.93, 2.46, and 2.10, respectively. The RIL ranged from 1.84 to 2.48

(Table 5). This trait variation was continuous, suggesting that the inheritance of it is complex (Fatokun et al., 1992; Tsilo et al., 2010). Transgressive segregation was observed in both directions (Figure 3) indicating a possibility to be used in selection for this and kernel related traits. Based on our results, it seems that low value of this trait means a kernel with a spheroid or round shape (short and plump) while a high value means a cylindrical shape (tall and thin).

The significant and negative correlation with kernel area ( $r=27$  at Prosper 2009 and 2010) and 1000-kernel weight ( $r=35$  at Carrington 2009 and 2010, and at Prosper 2009; and  $r=57$  at Prosper 2010) (Table 6) confirms the fact that spheroid shape seems to have more influence on kernel area and 1000-kernel weight than cylindrical.

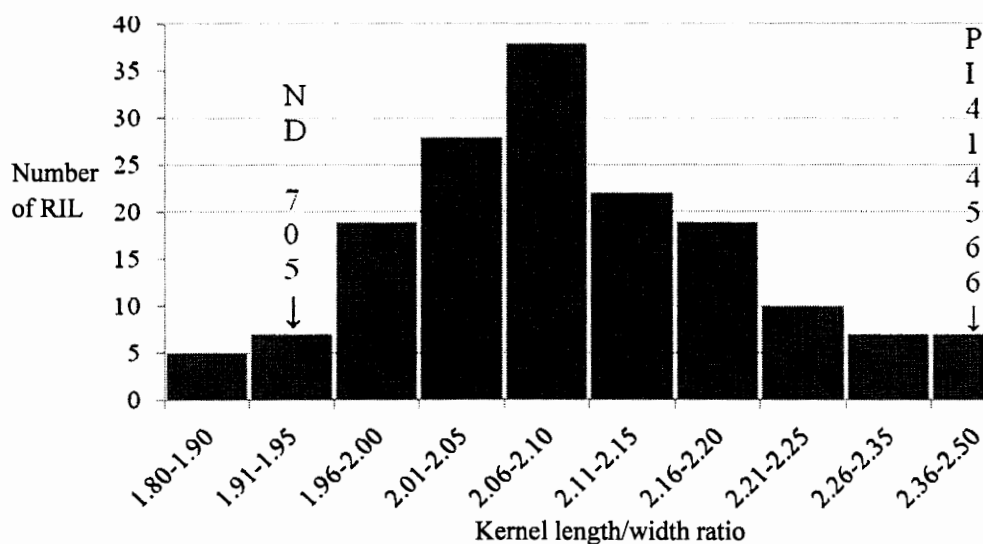

Figure 3. Frequency distribution of 160 RIL and their parents for kernel length/width ratio means over two locations (Carrington and Prosper), and two years (2009 and 2010) (Parental means are marked with arrows).

### Kernel area

The kernel area average across all environments was 11.76 mm<sup>2</sup>. ND 705, PI 414566, and RIL averages for this trait were 11.58, 9.53, and 11.76 mm<sup>2</sup>, respectively. The

RIL mean varied from 9.96 to 13.81 mm<sup>2</sup> (Table 5). The variable for kernel area was continuous, suggesting that this trait is complex and of polygenic inheritance (Fatokun et al., 1992; Tsilo et al., 2010). Transgressive segregation was observed on one direction toward a superior value of the best parent ND 705 (Figure 4). Due to the favorable conditions at Carrington, kernels were able to grow better at this location compared to Prosper. Within locations, the year of 2009 was more favorable for the expression of this trait than in 2010, except for PI 414566.

Kernel area was highly correlated with 1000-kernel weight (0.91) (Table 6). Previous studies by Bergman et al. (2000) and Breseghello and Sorrels (2007) also reported high correlation between these two traits. This correlation is a strong indicator for breeders to use the 1000-kernel weight to select indirectly for improved kernel area.

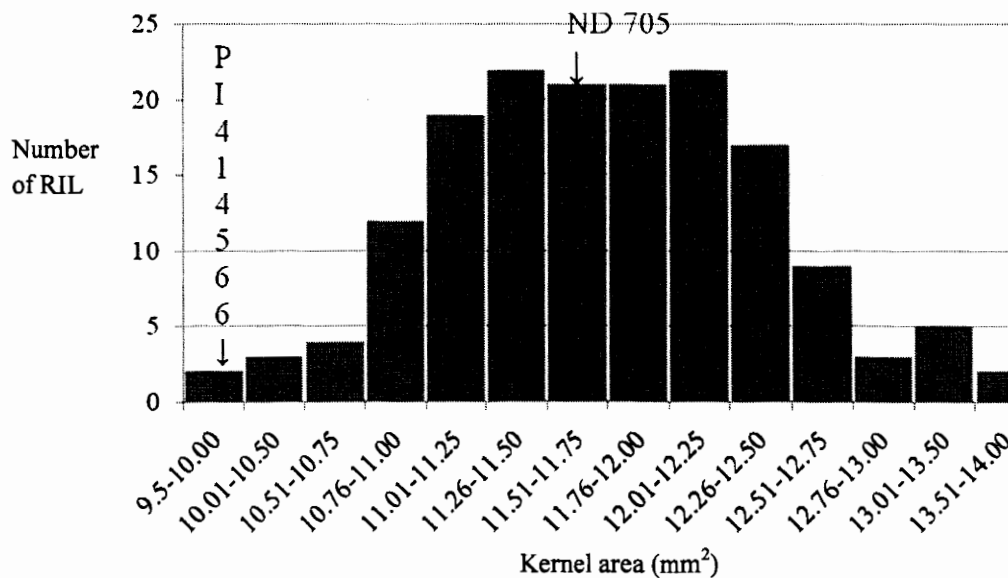

Figure 4. Frequency distribution of 160 RIL and their parents for kernel area means over two locations (Carrington and Prosper), and two years (2009 and 2010) (Parental means are marked with arrows).

## Kernel weight

The results of this study (Table 5) indicate that the mean for 1000-kernel weight across environments was 28.4 g while ND 705, PI 414566 and RIL means were 30.1, 16.0, and 28.4 g, respectively. The RIL ranged from 22.4 to 35.1 g. Kernel weight was, in general, higher at Carrington in 2009 followed by Carrington in 2010. Within the years of 2009 and 2010, Carrington had better environment conditions for wheat development compared to Prosper favoring kernel weight development. Kernel weight was highly associated with all the other kernel traits (Table 6). The kernel weight trait followed a continuous variation, suggesting that the inheritance of this trait is quantitative involving many genes (Fatokun et al., 1992; Tsilo et al., 2010). As for previous traits, transgressive segregation was observed for this characteristic as well (Figure 5) and it is what the breeders usually look for. It will allow them to select for improved kernel weight even when non-adapted parent are used in the cross. Kernel weight is largely influenced by environment conditions such as rainfall, temperature, and soil fertility (Daniel and Triboi, 2000).

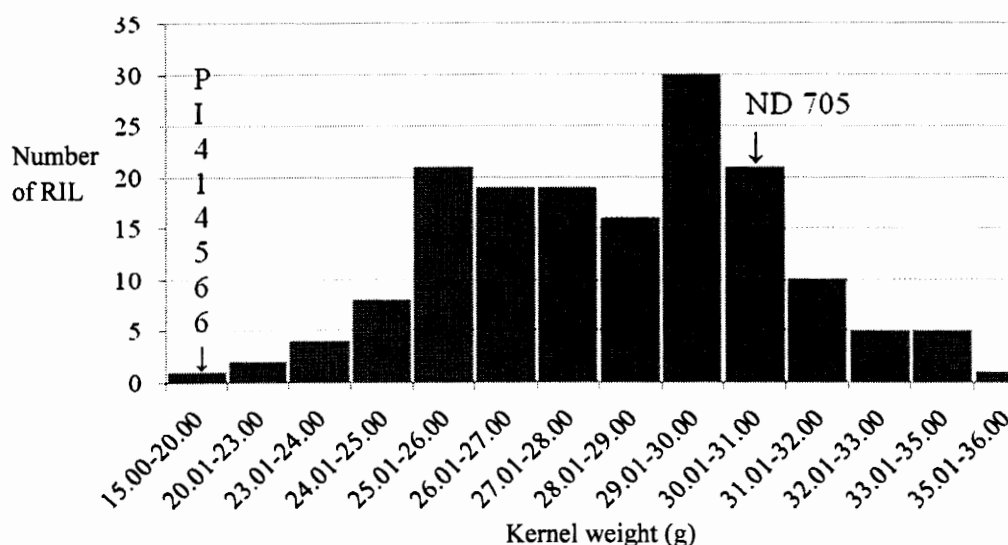

Figure 5. Frequency distribution of 160 RIL and their parents for kernel weight means over two locations (Carrington and Prosper), and two years (2009 and 2010) (Parental means are marked with arrows).

### **Associations among agronomic and kernel traits**

The grain yield mean of the RIL was lower than the adapted checks. This RIL population was developed to generate high divergence for kernel traits for mapping purposes. However, it also had high variation for agronomic traits.

Grain yield was highly associated with kernel traits. Grain yield was positively correlated with kernel width (0.26 at Carrington, and 0.65 at Prosper) and negatively correlated with kernel length/width ratio (0.29 at Carrington and Prosper 2009, and 0.51 at Prosper 2010) (Table 7). Overall, the top yielding genotypes in this study including the checks Faller, Steele-ND, and Barlow along with the RIL 143 had significantly higher values for kernel width. These results, seems to indicate that higher grain yield is associated more to kernels with spheroid shape. Also, the high correlations between grain yield and kernel area, and 1000-kernel weight (Table 7) suggest that these spheroid kernels should be large and/or heavy as well. The correlation between grain yield and kernel traits were higher at Prosper compared to Carrington. This higher correlation at Prosper suggests that under unfavorable conditions, the top grain yield genotypes, in addition to have better agronomic performance (low lodging, low kernel shattering, and diseases resistance), tended to have increased kernel width than kernel length.

Lodging was not a major issue except at Prosper 2010. Therefore, lodging was not correlated with kernel traits, except at Prosper 2010. At Prosper 2010, the significant correlation between lodging and kernel width, length/width ratio, area, and weight were -0.53, 0.45, -0.42, and -0.54, respectively (Table 7). These associations between lodging and kernels traits at Prosper in 2010 were similar to the results obtained for grain yield. The lodging resistant lines, in general, produced larger, heavier, and more spheroid

Table 7. Correlation coefficients (r) among the agronomic and kernel traits, and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The r values for single environment are denoted in the table

|                                     | Env     | Kernel length       | Kernel width         | Kernel length/width ratio | Kernel area          | 1000-kernel weight   |

<sup>a</sup> Correlation coefficients for a single environment.

type of kernels than those lines that lodged. Similar results were obtained for number of spikes per m<sup>2</sup> under the unfavorable environment of Prosper 2010. At this location, the genotypes with high number of spikes per m<sup>2</sup> tended to be associated with plump, large, and heavy kernels. Also, high number of kernels per spike as well as white spike color was significant correlated with large, heavy, and spheroid kernels. Plant height was significantly associated only with kernel area and weight. Tsilo et al., (2010) did not find significant correlation between plant height and kernel width, and weight.

The late lines tended to be associated with small (length and width) and light kernels. Tsilo et al. (2010) found similar results between days to heading and kernel traits. They suggested that late lines have less capability for grain filling compared to early lines.

#### **Associations among quality and kernel traits**

The highest values for grain protein content (GPC) were at Prosper in 2010 where climatic conditions were unfavorable. It seems that most genotypes have allocated nitrogen into protein development instead of grain yield. Kernel volume weight (KVW), kernel hardness, and flour extraction reached their highest values at Carrington in 2009 (Table 5).

GPC, in general, was not associated with kernel traits (Table 8). Compared to other kernel characteristics such as kernel size and/or shape, GPC is more affected by the environmental conditions, such as temperature, soil fertility, and rainfall (Daniel and Triboi, 2000), and certainly cultivar selection. However, some previous works showed significant correlations between GPC and kernel weight, width (Ohm et al., 1998; Tsilo et al., 2010), and length (Breseghello and Sorrells, 2007). These associations between GPC and kernel traits were attributed to a higher proportion of seed coat to the endosperm in

larger kernels by Marshall et al. (1984) or to a higher proportion of embryo size to endosperm as Breseghello and Sorrells (2007) proposed from their study.

KVW was highly correlated with all the kernel traits. It was negatively correlated with kernel length in all environments (0.26) except at Prosper 2010, whereas the correlation between KVW and kernel width was positive and very high (0.37 at Carrington, 0.63 at Prosper 2009, and 0.75 at Prosper 2010). Under unfavorable environment conditions, correlation between these two traits tends to increase. The correlation between KVW and kernel length/width ratio was highly negative (0.58) (Table 8). Based on these results, KVW seems to be closely associated with spheroid type of kernels. The correlations between KVW and kernel area and 1000-kernel weight also increased according to the intensity of environmental stresses. The correlation between KVW and kernel area was 0.36 at Prosper 2009 and 0.62 at Prosper 2010. No significant correlation occurred between these two traits at Carrington. The correlation between KVW and 1000-kernel weight was 0.38 at Carrington, 0.61 at Prosper 2009, and 0.79 at Prosper 2010 (Table 8). These results indicate that the type of kernels with higher KVW tend to be short in length, plump, large in area, and heavy. This type of kernel size and shape enhances the packing ability which results in higher KVW. These desirable kernel characteristics become more necessary as the level of environmental stress increases. Under unfavorable conditions, the kernel development becomes more restricted due to the lack of essential nutrients, water, and/or adequate temperatures. The genotypes with better efficiency for nutrients and water uptake, utilization, and conversion into kernels with the desirable traits described above tend to have good quality traits including KVW.

Table 8. Correlation coefficients (r) among the quality and kernel traits, and their significance for the RIL, their parents, and checks grown in four environments (Carrington and Prosper in 2009 and 2010). The r values for single environment are denoted in the table

|                                  | Env     | Grain protein content | Kernel volume weight | Kernel hardness      | Flour extraction |

<sup>a</sup> Correlation coefficients for a single environment.

Previous investigations on associations between KVW and kernel traits were in general conflicting. Troccoli and Di Fonzo (1999) found negative correlation between KVW and kernel length on durum wheat. The same authors reported that KVW was not significantly associated with kernel width, area, and weight. These researchers however, used small samples of only 25 kernels to measure the kernel traits. In other studies by Campbell et al. (1999) and Bergman et al. (2000), they used 78 RIL developed from a cross between a soft white (NY18) with hard white wheat (Clark's Cream) and found that KVW

was not associated with kernel length, width, and area. In these studies, kernel traits data were collected from 50 to 60 kernel samples. Lee et al. (2006) working with blended samples from two hard white wheat, 'Betty' and 'Trego', found however, significant positive association between KVW and kernel weight, and width. The kernel traits were measured in this study by the SKCS. Similarly, Ohm et al. (1998) also utilized SKCS for measuring the kernel traits and found significant association between KVW and kernel weight among 12 winter wheat cultivars. However, they did not find any association between KVW and kernel width. These inconsistent observations might have resulted from different growing conditions, wheat varieties/genotypes and classes, kernel traits evaluation methods, and kernel sample size.

The results on kernel hardness showed a negative association between this trait and kernel length (0.30), width (0.22 at Carrington, and 0.39 at Prosper 2009), area (0.26 at Carrington and Prosper 2010, and 0.54 at Prosper 2009), and 1000-kernel weight (0.18 at Carrington and Prosper 2010, and 0.45 at Prosper 2009) (Table 8). Previous study (Bergman et al., 2000) however, did not find any significant association between kernel hardness and kernel traits. Most of the investigations on kernel hardness indicate that this trait is affected mainly by genetic control (Pomeranz and Mattern, 1988), and probably in some cases by the interactions of proteins and starch granules (Greenwell and Schofield, 1986; Greenblatt et al., 1995).

Data from this study showed that flour extraction was significantly correlated with all the kernel traits including kernel width (0.27), length/width ratio (-0.22), area (0.19), and 1000-kernel weight (0.27), except kernel length (Table 8). Similar results were reported by Lee et al. (2006) who found high correlations between flour extraction and

kernel width, and weight. Breseghello and Sorrells (2007) reported the same QTL which resulted in an increase in kernel size and weight, also had a positive effect in flour extraction. Lyford et al. (2005) developed an equation to explain flour extraction in hard red winter wheat. In this study, kernel weight was one of the significant parameters influencing positively the flour extraction rate. Using a recurrent selection scheme for kernel size using 10 spring wheat genotypes, Wiersma et al. (2001) were able to increase flour extraction rate by 5%. Considering similar embryo size, larger kernels are supposed to have larger volume of endosperm, consequently, yielding in higher amount of flour extraction. Dai (2009) studied the changes of the main enzymes during grain filling period for large and small kernels. He found that enzymes related to starch synthase and accumulation, and ADP-glucose activities were significantly higher and more active in large kernels compared to small kernels. Plants with larger kernels maintained a longer period of kernel filling with greater activities of these enzymes during mid and late kernel filling stages generating a greater amount of starch. However, Breseghello and Sorrells (2006) using 95 soft winter wheat cultivars and samples of 24 kernels found significant association between flour extraction and only kernel weight at a single location. Other study (Bergman et al., 2000) did not find any significant association between flour extraction and kernel traits.

As it was reported for the K<sub>VW</sub> correlations with kernel traits, these inconsistent finding may be the result of different growing conditions where these researchers were situated, using different wheat varieties and belonging to different classes, different kernel traits evaluation method, and kernel sample sizes. However, flour extraction is a complex

trait and is not explained by one or few traits and will continue to be a great challenge for wheat breeders, millers, and industry.

## CONCLUSION

The parents, ND 705 and PI 414566, showed drastic differences for all kernel traits. Consequently, the RIL showed significant variation for all kernel traits. All kernel traits demonstrated continuous distributions suggesting the polygenic inheritance of these traits. Also, transgressive segregation occurred for all the kernel traits providing an opportunity for breeders to improve these traits. The kernel traits showed in general high association among themselves.

The genotypes had better performance for agronomic and kernel traits, K VW, and flour extraction at Carrington compared to Prosper due to favorable environment conditions. Within locations, except for flour extraction that had similar results at Carrington in 2009 and 2010, these traits were much higher in 2009 than 2010.

Grain yield, K VW, and flour extraction were highly correlated with kernel traits. These important agronomic and quality traits were correlated with kernel width, length/width ratio, area, and 1000-kernel weight. These results indicate that higher values for grain yield, K VW, and flour extraction are related to kernels with spheroid or round shape (short and plump). Also, these associations suggested that these spheroid kernels should be large and heavy in order to have better performance for grain yield, K VW, and flour extraction. Kernel traits can partially contribute to increase grain yield, K VW, and flour extraction.

Based on our results, breeders should considerer large, heavy, and spheroid kernels when selecting parental genotypes for the development of populations for improved agronomic and quality attributes.

<sup>a</sup> Traits were not evaluated in all the environments.

<sup>b</sup> Ratio: test of homogeneity (greatest EMS / smallest EMS) should be smaller than 10-fold.

- Traits were not collected at these locations.

## GENERAL CONCLUSIONS

The adapted (ND 705) and non-adapted parent (PI 414566) showed drastic differences for all the kernel, agronomic, and quality traits. Consequently, the RIL population showed significant variation for all these traits as well. All kernel traits had continuous distribution suggesting that the inheritance of these traits is quantitative involving many genes. Transgressive segregation occurred for all the kernel, agronomic and quality traits except for spike color and kernel volume weight (KVW).

Overall, the genotypes had better performance for kernel and agronomic traits, KVW, and flour extraction at Carrington compared to Prosper due to favorable environment conditions at Carrington during these two years. Within locations, except for flour extraction that had similar results at Carrington 2009 and 2010, these traits had higher levels in 2009 than 2010.

The checks Faller, Barlow, and Steele-ND along with the RIL 143 and 88 had significant superior grain yield across environments. The RIL 143 and 88 showed, overall, good agronomic attributes including low rates of lodging and kernel shattering, demonstrating high potential to be included in the HRSW breeding program. Also, the RIL 47 had superior attributes for KVW, and RIL 82 and 141 had superior attributes for flour extraction. These RIL can be valuable for the HRSW breeding program as well.

Grain yield, KVW, and flour extraction were highly correlated with kernel traits. These important agronomic and quality traits were correlated with kernel width, length/width ratio, area, and 1000-kernel weight. These results indicate that higher values for grain yield, KVW, and flour extraction were related with spheroid or round shape (short and plump) kernels. Also, these associations suggested that these spheroid kernels should

be large and heavy in order to develop genotypes with higher grain yield, KVV, and flour extraction. Kernel traits can play a significant role to improve grain yield, KVV, and flour extraction.

The use of elite x elite crosses continues to be the most common and effective type of crosses to develop new cultivars in breeding programs. However, with the concern that narrow germplasm may restrict breeding flexibility and slow genetic progress to biotic and abiotic stresses, it seems that the development of populations originated from adapted x non-adapted germplasm is a common practice by breeders to broaden the genetic variability of their germplasm and consequently increase genetic gain. This study has showed clearly the value of using non-adapted sources of germplasm to improve several wheat economic traits.

Based on this study, breeders should exploit heavy, large, and spheroid kernels during the parental selection for the development of populations with improved agronomic and quality attributes.
