This Master's Thesis is brought to you for free and open access by the Mechanical Engineering at UKnowledge. It has been accepted for inclusion in Theses and Dissertations--Mechanical Engineering by an authorized administrator of UKnowledge. For more information, please contact [UKnowledge@lsv.uky.edu](mailto:UKnowledge@lsv.uky.edu).

**STUDENT AGREEMENT:**

I represent that my thesis or dissertation and abstract are my original work. Proper attribution has been given to all outside sources. I understand that I am solely responsible for obtaining any needed copyright permissions. I have obtained and attached hereto needed written permission statements(s) from the owner(s) of each third-party copyrighted matter to be included in my work, allowing electronic distribution (if such use is not permitted by the fair use doctrine).

I hereby grant to The University of Kentucky and its agents the non-exclusive license to archive and make accessible my work in whole or in part in all forms of media, now or hereafter known. I agree that the document mentioned above may be made available immediately for worldwide access unless a preapproved embargo applies.

I retain all other ownership rights to the copyright of my work. I also retain the right to use in future works (such as articles or books) all or part of my work. I understand that I am free to register the copyright to my work.

**REVIEW, APPROVAL AND ACCEPTANCE**

The document mentioned above has been reviewed and accepted by the student's advisor, on behalf of the advisory committee, and by the Director of Graduate Studies (DGS), on behalf of the program; we verify that this is the final, approved version of the student's dissertation including all changes required by the advisory committee. The undersigned agree to abide by the statements above.

## ABSTRACT OF THESIS

### KINETICS OF WEDGE-TEE JOINT FORMATION DURING BRAZING OF AN ALUMINUM ALLOY UNDER CONTROLLED ATMOSPHERE

This work involves investigation of the kinetics data of a joint formation during aluminum alloy brazing. Data was generated by several groups of experiments conducted under conditions of a controlled oxygen level of the background brazing atmosphere. Generated data are examined to identify the phases of the joint formation and the time frame of its evolution. Specifically, the triple line kinetics data are analyzed to verify whether a power law between (1) the triple line of the molten metal preceding joint formation and (2) the formation time can be established for each formation phase. In addition, both initial and residual clad thicknesses on brazing sheets are studied to check phenomenologically an impact of silicon diffusion on joint formation. Formation shapes are also inspected in order to study if a 2-D configuration of joint formation is present. The kinetics data from different sets of experiments under adverse atmosphere conditions are compared to understand the impact of oxygen level on joint formation. This study is not necessarily aimed at building a mathematical model for T-Joint formation during brazing process, but intends to understand possible influential parameters on the development of the formation.

KEYWORDS: Aluminum Brazing, Kinetics, T-Joint, Background Atmosphere, Capillary Flow.

DEDICATION  
I DEDICATE MY THESIS TO MY FAMILY

## ACKNOWLEDGEMENTS

First of all, I want to take this opportunity to sincerely thank my academic advisor Professor Dusan P. Sekulic for his guidance for my graduate study. Without his support, this research work would never have been completed.

In addition, I am grateful to my committee members: Drs. Kozo Saito and Haluk Karaca. I would like to thank all of you for your time and advice during the defense process.

I also want to thank all the members of the Department of Mechanical Engineering for the assistantship to support my study and living in the United States.

Last but not least, gratitude is also given to all my team members in our laboratory for their precious suggestions and help.

## CHAPTER 1: INTRODUCTION

### 1.1 Background and Motivation

Aluminum alloys brazing has been playing a significantly important role in numerous applications for a long time, such as in aircraft applications and compact heat exchanger manufacturing.<sup>1,2</sup> Key physics phenomenon involved in Aluminum brazing is a surface tension/capillary driven flow of microlayers of molten metal around the interface of two mating metals.<sup>3</sup> The liquid phase metal wets the surfaces of bonding metals and spreads on them due to capillary action and finally becomes solidified to form the joint. The detailed reviews of spreading phenomena and the dynamic aspects of capillary flow are available.<sup>4-6</sup> In ref. 6, a theoretical model of a power law type, spreading distance  $\sim t^{1/2}$ , is proposed to describe the triple line location dependence on time. This relationship has been derived by balancing the capillary and viscous forces only.

Kinetics study of this flow family is crucial in manufacturing industry. For example, in the field of heat exchanger manufacturing, both the final shape and dimension of joint formation and the duration of the heating sequence of fin tubes being brazed in the furnace on a moving belt are the two of deciding parameters to determine the quality of joints and reduce probability of poor thermal contact resistance between fins and substrate surfaces. To ensure better mechanical integrity of a heat exchanger, all the joints must have well formed fillets. In recent years, a lot of attention has been given to kinetics phenomena during brazing, such as a study of a sessile drop molten metal spreading over complex substrates and capillary rise of liquids.<sup>7,8</sup> However, most of the research of the so called T-Joint formation is mainly focused on its equilibrium state, not its evolution. Reference 9 offers a study of joint formation of a traditional and a novel fluxless brazing sheet under different background atmospheres.

This thesis summarizes the characteristics of T-Joint kinetics based on an experimental work involving molten aluminum alloy spreading over aluminum substrate.

## **1.2 Objectives**

Objectives of the study summarized in this thesis are as follows:

- To conduct a literature review of related topics that are of importance to this thesis and to summarize the existing knowledge
- To present five groups of kinetics data of T-Joint formation from a fluxless substrate and over a non-clad vertical aluminum alloy mating surface under the wide range of oxygen levels including: 70ppm, 200ppm, 500ppm, 2,000ppm and 200,000ppm Oxygen, respectively
- To verify whether a power law exists between the joint triple line location and time
- To identify the distinct phases of a joint formation and the time frame of each so identified phase
- To validate if a 2D configuration of joint formation can be secured under given background atmosphere conditions
- To examine whether silicon diffusion has a sizable presence and/or an impact on joint formation in each group

In the subsequent chapters, these objectives will be further expanded.

This work has been conducted within a scope of the project titled “Reactive and non-reactive wetting of liquid metals on rough surfaces. Experiments and modeling”, Principal Investigator Prof. D.P. Sekulic, NSF – CBET Grant # 1235759.

### 1.3 Literature Review

To better understand the existing depth of knowledge about the kinetics of a wedge T-Joint formation (spreading into a “corner”) during aluminum brazing over, in general, a reactive substrate, an extensive literature review has been performed. The remaining content of this chapter offers the review divided into several sections depending on the related topic.

#### 1.3.1 Capillary Driven Wetting and Kinetics

Capillary action is the driving force in applications of a process involving wicking phenomena over rough/porous surfaces. In the study of Bico et al. concerning wicking of silicone oil over a micro-structured surface with regular micron-sized topographic alterations of a substrate formed by spikes composed of a silicon wafer and a sol-gel silicate coating<sup>10</sup>, a Washburn type kinetics<sup>6</sup> model was well established except that an empirical parameter is required for executing a modeling. The same phenomenon was studied by Hay et al.<sup>11</sup> Wicking was treated as spreading over a surface featuring parallel channels. Washburn type kinetics results were also obtained. Ishino et al.<sup>12</sup> confirmed that wicking kinetics in a network of regularly distributed micropillars was strongly correlated to the ratio of pillar height to the pitch of the network. The work from Chen et al.<sup>13</sup> involved numerous structured surfaces with a series of uniformly distributed patterns of regular geometric shapes such as star and square pattern surfaces. Its kinetics results conformed to Washburn type kinetics model. In Ref.8, the wicking kinetics of five organic liquids with different surface tension to viscosity ratios<sup>14</sup> were studied during spreading over an intermetallic surface with locally non-uniform surface structure but homogeneously distributed over a vertical substrate. Since the Bond number associated with selected liquids was very small ( $O(10^{-9})$ ), the influence of gravity was neglected in the subsequent model building. This modeling was focused on the rise of a liquid driven by the capillary force.

Assumptions were made for theoretically building the kinetics model. The influence of evaporation of the organic liquids is neglected due to the fact that the saturated liquid vapor atmosphere was in contact with the liquid phase. An infinitely large liquid source is assumed (compared to the liquid phase climbing through the roughness features of the surface). By invoking Darcy's law and the definition of velocity, an equation that correlates the rising triple line location of the liquid to (i) permeability, (ii) tortuosity, and (iii) dynamic viscosity of the rough surface is devised. A particular triangular cross section area of the V-shaped groove is assumed. Using the expressions<sup>15</sup> for cross section and capillary force for a V shaped groove and introducing the definition of the filling factor<sup>7</sup>, the relationship relating moving front to time was derived. It was noted that the capillary rise of liquid over the studied complex surface follows a Washburn type model. Scaling time with the surface tension to viscosity ratios collapses data around a narrow domain. This means that the scaling of the time eliminates the fluid type effect on wicking, implying that all considered liquids penetrate the porous surface following the same governing law. This was associated with a constant filling factor.

Capillary action is also the dominant force for the molten metal clad spreading on the substrate and subsequent joining of the materials that are to be bonded. However, there is a significant difference between a low temperature and a high temperature capillary phenomena.<sup>16</sup> For example, molten filler metal spreading over substrate may interact with a substrate what may not be the case with silicon oil on a non-reactive substrate. This difference may also lead to a different time scale for kinetics<sup>17</sup>. In Ref.7, Wen et al. studied the capillary driven flow of molten Sn-Pb eutectic of a sessile drop over a Cu-Sn-based complex substrate that has microscallop-grain topography. The mathematical model for this spreading during a soldering process has been

built. Relationship between spreading front and the evolution time has been performed. The kinetics data clearly indicate that the process of spreading can be divided into three stages:

- 1) The initial stage dominated by inertial forces which lasts very short [ $O(10^{-1} \text{ s})$ ] for spreading over a flat nonreactive surface<sup>18, 19</sup>.
- 2) The power-law stage. This is the main stage which covers a great portion of the spreading time [ $O(10^0\text{-}10^1 \text{ s})$ ].
- 3) Asymptotic stage featuring a diminishing slope due to a diminishing liquid source.

The model was built for power-law type of spreading stage, controlled by surface tension and viscosity. The complex scallop shaped surface was simplified and represented as a collection of hexagonal elements which formed a surface roughness with triangular-shaped grooves and merging zones. Several assumptions were made before building the theoretical model, including constant liquid phase properties and negligible gravity impact. Also, chemical reactions during spreading were considered as negligible. Using the continuity equation and the Darcy's law for a differential control volume<sup>20, 21</sup> gives a relation between the location of triple line and the spreading time. The relationship is of a Washburn type. The instantaneous locations of the spreading front are directly proportional to the square root of the spreading time. This model agrees well with the empirical data, with a deviation in the range of 5-15%.

Sekulic<sup>22</sup> used scaling analysis on governing equations for reactive filler metal micro layer flow in a sessile drop configuration before the formation of an equilibrium membrane of the free surface during aluminum brazing to find a series of dimensionless parameters that control this process. Five governing equations are identified for this analytical model, involving 3-D configuration. These equations include: (i) continuity (ii) momentum (iii) energy (iv) concentration of a single species, and (v) entropy. These equations are further

simplified based on empirical evidence (i.e., two-dimensional features, constant thermo physical properties, no gravity influence etc.) After that, boundary and initial conditions were imposed on those simplified governing equations including temperature and velocity at top of the substrate (bottom of the clad) and the involvement of balancing normal and tangential stress components<sup>23</sup> at the free surface. Subsequently, a number of relevant scales are selected for length, velocity and time. Finally, rewriting the simplified governing equations with selected associated scales resulted in an extraction of the prominent dimensionless numbers for the process. These include Reynolds number, Prandtl number, Schmidt number, Bond number, Capillary number and Reaction number. [Ref. 22]

Many industrial processes are based on the control of the flow and spreading of high temperature liquids<sup>24-26</sup>. However, high-temperature spreading is a complex phenomena<sup>27</sup>. So, this research has to contribute to an insight into the physics of the process, capillary evolution of the liquid metal interface.

The difficulty in modeling of this process lies in the phenomena that take place at nano or atomic scale in the vicinity of the triple junction with macroscopic phenomena such as the movement of the liquid front<sup>27</sup>. Atomic theory and experimental research along with computer simulation is clearly benefiting from analysis and experiments conducted at the macro scale. Hence, a connection can be established to identify the similarities while pointing out the fundamental differences. A key aspect of the analysis is to divide the process into constituent steps and understand the relative kinetics of the movement of the liquid front and the accompanying phenomena such as adsorption, ridging, dissolution and compound formation in order to define the instantaneous structure of the triple junction. By doing this, a general theory can be modeled

concerning spreading kinetics under high temperature condition<sup>27</sup>. The goal is to formulate a united theory for both high and low temperature spreading.

### **1.3.2 Background Atmosphere Impact on Joint Formation**

Controlled Atmosphere Brazing (CAB) is an advanced technology in aluminum brazing process for manufacturing. During brazing, flux on aluminum surface is required to destabilize and destroy native oxide film so that the molten clad can flow freely<sup>28</sup>.

Atmosphere quality is one of the most significant variables in the brazing processes. However, in practical industrial applications, it may be overlooked and poorly controlled<sup>29</sup>. And lack of attention has profound impact on the process outcome.

In the case of brazing in Vacuum furnace, discoloration of the brazed part is associated with leak during the heating cycle prior to reaching brazing temperature<sup>29</sup>. This can be attributed to abnormal partial pressure of oxygen in the furnace, which is the primary controlling factor deciding the proper wetting of molten filler metal on the substrate and flow into the joint clearance.

A classic indication of a leak in the CAB furnace atmosphere is an increase in the dew point reading during a brazing process. This is because of the large concentration difference of constituents, such as nitrogen, oxygen and water, between in-furnace atmosphere and out-furnace atmosphere so that the oxygen and moisture will infiltrate into the system if the leaks are present. In order to ensure a good background atmosphere for the furnace brazing, the dew point temperature must be monitored to maintain low humidity.

Measuring the dew point of the gas atmosphere at brazing temperatures by using a continuous-recording dew point instrument is mandatory.

Both the effect of the oxygen level and the humidity magnitude was studied recently experimentally in our laboratory by using the hot stage microscopy and a controlled atmosphere brazing furnace, with samples featuring variable clearance along the interface of bonding metals<sup>9</sup>. It was found that for traditional brazing sheets, where the external fluxes must be used (the sheets consist of an Al alloy substrate and an Al-Si alloy clad), different oxygen level conditions do impact the joint formation and modify the uniform spreading in particular if the oxygen level is above 200 ppm. When the oxygen level reached 500 ppm, non-uniform spreading of molten metal over the substrate was often noticed. Increasing the oxygen level to 2000 ppm results in an increasingly inconsistent and ultimately poor joint formation and in some samples, molten clad failed to spread. When the furnace chamber was filled with air, it was noted that there was no bonding for all samples. As to the influence of humidity, high humidity had a negative impact on the joint formation which can be observed by measuring the joint length along the variable clearance direction, as will be elaborated in detail later.

### **1.3.3 Topography of Joints and Silicon Diffusion into the substrate**

Aluminum brazing plays a major role in the field of heat exchanger manufacturing. A superior material selection such as an AA3003 aluminum alloy bears the merits of high thermal conductivity, low cost and good resistance to corrosion. Industry utilizes empirical methods to control the brazing process. However, these methods do not always work properly due to the lack of thorough understanding of brazing mechanisms. Hence, studies have been conducted in the field of Aluminum brazing including topography of joints and silicon diffusion into the substrate.

Formation of brazed joints is influenced by many variables which directly or indirectly determine the quality of joints such as assembly configuration, the gap between the bonded parts and the volume of the joints. For example, if the gap is too large compared to the available clad volume, the joint may not occur because capillary flow of the melting metal is not capable of bridging the metals to be joined<sup>30</sup>. However, if the gap is too small, the effluents formed at the peak brazing temperature may result in the gas entrapment within the clearance gap which can bring about the generation of voids that severely reduce the strength of the joints<sup>31</sup>. The influence of joint topology on the 2D and 3D formations of brazed joints was discussed<sup>32, 33</sup> with respect to configurations that are similar to the ones found in the field of compact heat exchanger manufacturing. In this study, joint topology is characterized by the following variables: 1) the geometry of the bonding surfaces; 2) the gap between bonding alloys; 3) gravity influence on the joint orientation; 4) the volume of the joint. Several dimensionless parameters were used to define these variables. The finite element method employed is based on minimizing the potential energy of the free surface prior to the onset of solidification. This is facilitated numerically, through a numerical method developed.<sup>34,35</sup> Minimizing the overall energy of the surface results in an equilibrium joint topography shape. The results then were studied to identify the influences of topographical parameters on the spreading length along the bonding surfaces. It is demonstrated<sup>36</sup> that if the mass of the filler metal forming the joint is accurately predicted, topology of joint formation can be determined by using a numerical method proposed. Experimental results have shown that the mass flow rate of the molten filler metal was related to<sup>37</sup>: 1) Si-content; 2) cladding ratio; 3) ramp-up rate; 4) peak brazing temperature; 5) flux converge. However, it is difficult to simulate the dynamics of the clad flow due to the complexity of non-linear, transient, and spatially distributed transport

processes<sup>38</sup>. Moreover, it is not possible to directly (without an empirical input) determine the clad mass that forms the brazed joint. In Ref. 37, prediction of the molten clad mass at the onset of solidification was based on the main hypothesis that joint mass is equal to the clad mass difference between initial clad mass and the residual mass. Several other assumptions were also made to solve this problem: 1) Constant densities of all phases; 2) The clad alloy phase change takes place under either equilibrium or non-equilibrium conditions; 3) The solid phase from the mushy zone is distributed evenly and separated from liquid after molten metal flows to the joint area; 4) Mechanical deformation and its influence on clad layer are ignored; 5) The erosion effect on the substrate alloy will not influence the final equilibrium membrane shape at the free surface at the onset of joint solidification. By adopting an approach to minimize the potential energy, the finite element method was implemented and the numerical results were compared to empirical data (the wedge-T and header-tube joints). It was concluded that the main mass balance assumption was proven to be valid. 3D joint topology can also be predicated with an acceptable error (if erosion and 3D effects are not influential and if the residual formation is known). In addition, non-equilibrium Si-diffusion controlled melting process must be considered to predict the brazed fillet size. In order to predict the clad mass flow into the joint, an essential part for this modeling lies in obtaining the mass of the residual clad on the substrate. It was noticed<sup>39</sup> that the residual clad layer formed over the whole substrate consists of primarily  $\alpha$ -Al phase<sup>40</sup> and had a uniform topography. With this observation, the volume of the residual clad metal can be calculated by measuring the uniform residual clad thickness, which will assist in predicting the mass of the residual clad assuming constant density of the clad/filler for all phases. The residual mass obtained was subsequently utilized to determine the clad mass flow into the joints prior to the onset of solidification. All previous discussions about joint topography are based on the hypothesis<sup>41</sup>

that the controlled atmosphere brazed aluminum joint shape is defined by the shape of the molten metal equilibrium membrane at the onset of solidification. This is confirmed in the study<sup>42</sup> which also revealed that the joint formations are dominated by surface tension, with less influential parameters such as gravity, dissolution phenomena and subsequent solidification.

Brazed joints are formed by a spreading of liquid phase of the filler metal, hence wetting the substrate that is to be joined to another aluminum alloy mating surface is important. The volume of the liquid formed is critical for good brazeability and has an influence on the formation of a sound metallurgical attachment in order to guarantee a proper bond (and an ultimate function of the device featuring this bond)<sup>43</sup>. That amount is also dependent on the clad composition, the peak brazing temperature and clad/core interactions due to silicon diffusion. Insufficient liquid formations, as well as an excess liquid bring both negative impacts on the joining process, such as incomplete bonds and an increased local core dissolution<sup>44</sup>. During brazing, Si diffusion from the clad into the core has been observed and well researched. Si diffusion is due to the relative richness of a solute in the clad<sup>45</sup>. For example, solid-state interdiffusion prior to melting leads to a suppression of the liquid formation due to Si depletion within the clad<sup>46</sup>. Differential scanning calorimetry (DSC) method was used by Turriff et al.<sup>47</sup> to measure the amount of liquid fractions for the case of aluminum brazing sheet with AA3003 Si-lean core and AA4343 Si-rich clad. It was noticed that during heat-up stage, the initial amount of liquid formed is not significantly decreased as a consequence of the clad/core interactions. But the liquid fraction is gradually decreased and can be totally removed by diffusional solidification. Furthermore, a prolonged soak time at elevated temperature (>1 h at 500 °C) does not contribute to a suppress mechanism reducing availability of the initial amount of liquid formed. However, it was found<sup>47</sup> that the presence of the

liquid phase above the Al-Si eutectic temperature appears to improve Si absorption by the core and speeding the rate of decrease of molten clad during the brazing cycle.

Based on the fact that a solid state Si diffusion before melting modifies alloy's composition on both sides of the clad-core interface of the brazing sheet and that Si diffusion in the clad subsequently dominates the melting process, a mathematical model through non-equilibrium diffusion-controlled melting was proposed<sup>48</sup>. This was done to evaluate the residue thickness after brazing on the substrate. The sum of the spatial domains caused by the solid phase diffusion prior to melting<sup>49</sup> and that of diffusion controlled melting leads to the total residue thickness. The model was then solved numerically in terms of Si concentration distribution for a moving boundary case. The numerical results were then compared to experimental data of AA4343/AA3003 brazing sheet, demonstrating a good agreement. In addition, it was indicated that the residue formation is strongly dependent on the grain size of the Aluminum clad composite matrix. Gao et al.<sup>50</sup> demonstrated the importance of the determination of the Si diffusion coefficient for modeling joint formation, in particular during the heating segment<sup>32, 33</sup>. In the study, diffusion coefficients of Si were determined in both the joint and residue area in order to analyze silicon migration across the clad-core interface of an Aluminum brazing sheet. It was found that the local variations of diffusion coefficient are noticeable. Subsequently, these coefficients were used to evaluate the joint formation and the predictions were compared to empirical data with a satisfactory agreement.

### **1.3.4 Summary of Literature Review**

Spreading of molten metal clad that forms the joint formation is a phenomena driven by capillary action / surface tension. Several models that govern the

surface tension dominated regime have been raised which conform to Washburn type model. In addition, the formation topology in the equilibrium state and silicon diffusion in the clad was well researched and numerical methods to predict the topology and residual thickness were proposed. Besides, it is demonstrated that In a Controlled Atmosphere Brazing furnace, the oxygen concentration and humidity are two influential factors that determine the quality of brazed joints.

However, the kinetics of joint formation of aluminum brazing in a wedge-Tee configuration on a more or less reactive substrate has not been generally studied. These joints are typical in the field of compact heat exchanger manufacturing. Hence, a study such as this thesis work focusing on such phenomena is imperative.

## CHAPTER 2: EXPERIMENTAL EQUIPMENT DESCRIPTIONS

Brazing tests (sample configuration given in Figure 2.1) were performed in Optical Contact Angle (OCA) Measuring System. To control the atmosphere in the chamber, nitrogen or compressed air has been supplied to the chamber for a certain amount of time before starting the heating procedure. During the test, the OCA frame panel and hot zone windows were cooled by water at room temperature. The exhaust temperature was controlled before rejecting the effluents to the atmosphere.

### 2.1 Optical Contact Angle (OCA) Measuring System

The traditional Optical Contact Angle measuring system (OCA 15 plus), manufactured by DATA PHYSICS<sup>51</sup>, has been modified for controlled atmosphere operation. It is capable of measuring both static and dynamic contact angle<sup>4</sup> during liquid spreading over the surface at both room and elevated temperatures. In order to study a high temperature wetting and spreading phenomena of molten metal, such as soldering and brazing, the traditional OCA 15 plus system has been modified to OCA 15LHT plus by adding a High Temperature furnace (HTFQ 1200). To accommodate our need for a controlled atmosphere, the hot zone chamber has been modified radically. The original glass tube has been replaced with a thermally conductive ceramics tube which has better thermal conductivity than glass ( $K_g = 1.4 \text{ W/m}\cdot\text{K}^{52}$ ,  $K_c = 25 \text{ W/m}\cdot\text{K}$  at  $300 \text{ K}^{53}$ ) and is capable of enduring high temperature ( $T_{cm} \approx 1800 \text{ }^\circ\text{C}^{52}$ ). The OCA 15LHT plus unit, as seen in Figure 2.2, can sustain up to  $1500 \text{ }^\circ\text{C}$  in the central zone of the hot chamber of the ceramic tube. Special decoupling inlet and outlet windows, cooled with circulating coolant fluid (water) to keep the temperature of transparent quartz windows not too high, are designed specifically for the experimental program of the NSF sponsored project of which this Thesis work is a preliminary research effort.

The thermal condition of the furnace can either be controlled manually, by specifying a desirable temperature from the panel of a dedicated control unit (see Figure 2.3) or by a temperature program. This program is created in SCA20, a graphical user interface operating software for the unit installed on the dedicated computer. Two temperature values of the heater are displayed on the panel and:

$$|T_{H1} - T_{H2}| \leq 3^{\circ}\text{C}$$

during the experiment.

A typical operating software interface of SCA20 for this work is shown in Figure 2.4. Since attention must be given to information displayed on the computer screen throughout the experiment, software temperature control is used in this work. Experimental sample is positioned at the center of the ceramics tube to maximize the uniformity of the hot zone temperature field and the corresponding heat transfer rate. There is one additional built-in thermocouple at the center of the tube. However, its position in the tube is below the axis of cylindrical tube (no direct contact between sample and this thermocouple), Figure 2.1. The temperature measured from this thermocouple is the temperature representing hot zone atmosphere temperature at the given location. In view of this, an additional external K-Type OMEGA thermocouple (Part No. KMQXL – 020U-12) for measuring the sample temperature is installed. This thermocouple is attached to the bottom face of the substrate (See Chapter 3 for details) and is connected to the data acquisition system of National Instruments Cdaq-9172 module connected to the dedicated computer. The external thermocouple reading is displayed on the computer through a program created by LabView. For the brazing experiments of AA3003 alloy in the furnace, the sample temperature during brazing cycle is adjusted so that the clad will be exposed to a temperature that corresponds to alloy melting in the range of 569°C-579°C and a dwell time of ~15 minutes. After the joint formation starts, temperature will rise slowly with the average rate of 4°C per minute and finally the temperature reaches 595±5 °C. (See Chapter 3 for details)

reading 5 — Temperature recording button 6 — Temperature profile selection button

The background of the ceramic tube's free cross-section area is illuminated by a Halogen diffuse light. The appearances of the cross-section (and any objects within it) were recorded by a CCD camera aligned with the axial axis along the hot zone so that spreading kinetics can be observed on the computer screen using SCA20. The relative position of the height of the tube hot zone and the camera-telescope assembly central axis can be adjusted to ensure that the camera, furnace chamber and light source are all aligned in the axial direction. The hot zone can also be rotated in the horizontal plane so that the tube opening can face the operator for manipulating the sample.

## **2.2 Purging System**

Purging system is employed to eliminate residue gas from the furnace chamber and achieve controlled low oxygen level (i.e., a desirable atmosphere in the chamber). A precisely controlled oxygen concentration of the fluid stream at the inlet port allows studying the effects of oxygen level on the kinetics of joint formation. The gas control system includes calibrated composition gas sources, associated regulators, a flow meter and the connecting tubing that links gas sources with OCA 15LHT. See Figure 2.5 for details. The sources are coming from five pressure vessels delivered by Scott-Gross Co. containing Nitrogen or compressed air with 5 different oxygen level ( $O_2$ ) concentrations: 2 ppm, 210 ppm, 501 ppm, 2003 ppm and ~200,000 ppm. Please note that the actual oxygen concentrations of purging gases for furnace chamber are continuously monitored in an oxygen analyzer that is connected to the exhaust gas outlet of OCA 15LHT unit (See 2.8)

The gage pressure for the gas at the vessel outlet is controlled to be 210 kPa read from the regulator keeping the chamber purged to desirable atmosphere within a reasonable time. For experiments using Nitrogen as purging gas, the furnace

chamber was purged for 2 hours with a flow rate of  $500 \pm 2$  ccm, that is,  $\frac{5}{6} \times 10^{-5} \pm \frac{1}{30} \times 10^{-6} m^3/s$ . The inner diameter of the ceramic tube hot zone is 40 mm with a length of 330 mm. Thus, with the constant flow rate, in a 2-hour time frame, the air volume in the ceramic tube can be replaced for about 145 times to ensure that a desirable atmosphere under controlled purging source is reached.

### 2.3 Cooling System

For the proper operation of the transparent windows at the two end ports of the hot zone, as well as for safety of the operating personnel and extended service life of equipment, a cooling system is installed for the OCA furnace unit. The cooling system is composed of two sub-systems: (1) Exhaust gas cooling and (2) Flange and frame water cooling

The objective of the exhaust gas cooling is to secure the exhaust temperature of the gas at the exit port to get close to the surrounding room temperature before it

is rejected to the outside atmosphere. This objective can be easily accommodated with a simple metal pipe exposed to free convection in a vertical orientation. A corresponding heat transfer calculation model has been devised to predict whether the task will be achieved with the pre-defined length of the copper tubing. A 45cm long copper pipe, as seen in Figure 2.2, is used to connect the hot exhaust gas outlet to a polyethylene tube which is then connected to laboratory roof for releasing exhaust. Based on convective and radiation heat transfer calculation, it is inferred that the copper pipe selected is capable of reducing gas temperature of the low mass flow rate stream under OCA unit's maximum operating temperature. For practical consideration and to secure additional safety margin, a 45cm long copper pipe is installed.

The water cooling system, as seen in Figure 2.6, consists of a water pump manufactured by EHEIM, a tank filled with 14L water from laboratory and associated tubing. The pump takes the cooling water from the tank and delivers it to the flange at either side of the furnace as well as to the furnace frame for cooling. The heated water subsequently returns to the tank and it is mixed with the surrounding water. At any instant, the thermal capacity of the water stream reduces the furnace mantel temperature significantly. Thus, the heat delivered to the tank from the returning water is small and temperature of water in the tank can be assumed to be virtually constant at the room temperature of 26 °C as seen in Figure 2.7. The water cycle is shown in Figure 2.9.

**Figure 2. 6** Water cooling system

1 — Returning tubing 2 — Water tank 3 — Pump inlet tube 4 — Pump outlet tube 5 — Pump

Figure 2. 7 Temperature of water in the tank

### 2.4 Exhaust Gas Oxygen Level Monitoring System

In order to ensure that the furnace atmosphere is under a prescribed and controlled oxygen level, the exhaust gas outlet PVC tube is connected to a trace oxygen analyzer manufactured by Teledyne Analytical Instruments (316RA) as seen in Figure 2.8. The oxygen level history was recorded at desirable time interval. The analyzer is not suited for measuring the oxygen level of the compressed air<sup>54</sup>. To protect the instrument from potential harm, the compressed air runs are not monitored by the analyzer. Instead, the oxygen level in the compressed air is assumed as for the atmosphere air, i.e., 200000 ppm, as specified by the gas provider (Scott-Gross Co.)<sup>55</sup>. The connecting line schematic is shown in Figure 2.9.

Figure 2. 8 Trace oxygen analyzer

## 2.5 Experimental System Schematic

The OCA units, the controlling units, the flow meter and the dedicated computer are positioned on an optical table manufactured by MELLES GRIOT (Part # OTTR-305-1219-2438-M6) with controlled vibration system.

Figure 2.9 shows the system schematic for the experimental work.

**Figure 2.9** Experiment system schematic

## CHAPTER 3: MATERIAL PREPARATION AND EXPERIMENTAL PROCEDURES

The sample joint formation configuration is monitored under controlled atmosphere conditions. The procedure includes test sample making involving clad thickness inspection, oxygen level and temperature recording during joint formation tests, data analysis and post-test sample examination.

The test designations and conditions associated with each test can be referred in Appendix 2.

### 3.1 Sample Preparation

#### 3.1.1 Sample Configuration

The isometric and top views of the sample are shown in Figure 3.1 and Figure 3.2, respectively.

Figure 3. 1 Isometric view of sample configuration

Figure 3. 2 Top view of sample configuration

The sample assembly is mainly composed of three rectangular parts:

(1) One 40×76×1.1 mm copper plate for holding T-joint samples. The plate is inserted at the center of the ceramic tube of the hot zone (see Figure 2.2 for the configuration). The plate is positioned freely in the tube, horizontally to ensure that the substrate is located at the centerline position within the hot zone.

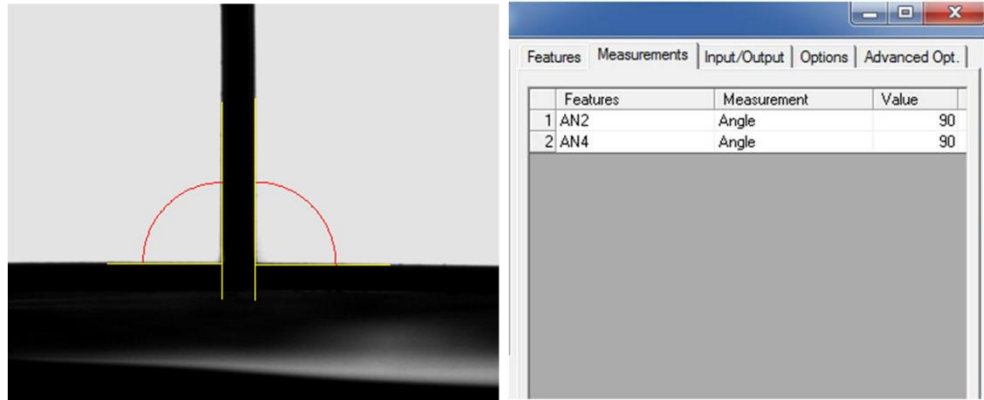

(2) One 37×20×0.31mm clad substrate (brazing sheet) is positioned on the copper plate (see Figure 3.2). The substrate is made of Al-5%Si clad with an A3003 core<sup>9</sup>. No flux is required for brazing in the furnace.

(3) One 15×15×0.4 mm vertical A3003 piece represents the mating surface (see Figure 3.1). This piece is fixed on the substrate by two stainless steel wires with a diameter of 0.4mm wrapping the bottom of the copper plate to the top edge of the vertical piece.

All raw materials were first manually cleaned with 95% ethanol and then ultrasonically cleaned with 95% ethanol for ~ 2 minutes in order to eliminate any oil or chemical residues. The materials were dried in air for subsequent use.

The K type external thermocouple mentioned in 2.1 is placed at the left side of bottom face of the substrate as shown in Figure 3.2. Its tip is intentionally bended lightly upward to guarantee it is in intimate contact with the brazing sheet. This thermocouple is capable of measuring temperature in the range of 0 °C ~ 1335 °C and with measuring deviation  $\pm 1.5$  °C at 590 °C<sup>56, 57</sup>.

The sample is positioned in the chamber horizontally with a deviation from horizontality of 1.5° maximum. The small deviation limit imposed is assumed to have a negligible impact on the joint formation. The angle between vertical piece and the substrate is measured by Image-Pro software as shown in Figure 3.3 in order to control the angle between the mating surfaces within the range of  $90^\circ \pm 1.5^\circ$ .

**Figure 3. 3** Measurement of angel between vertical piece and substrate

### 3.1.2 Clad Thickness Uniformity

All the clad sheets in this work were taken from the same piece of an original clad sheet material. However, these sheets were manufactured by hot rolling under laboratory conditions and there is a possibility that some samples may feature a variable clad thickness, primarily within the edge zone orthogonal to the longitudinal direction of observation. Hence, before analyzing kinetics data, a clad thickness study must be conducted to verify whether a uniform thickness of the clad exists, and to ensure that all the brazed samples have the same initial conditions.

Three test samples and three test edges are randomly chosen, extracted from the 40×60 mm original clad sheet materials as shown in Figure 3.4. The attention was paid in particular to the edge zones. A uniform clad thickness has been established at the center along the longitudinal sheet direction, what may in principle not be the case with the lateral locations.

These test samples are partitioned, resin mounted, polished at edges and the cross-section were etched. They are ultimately observed by using a Nikon EIPHOT 300 microscope and recorded by using a dedicated the computer to measure in situ the clad thickness before brazing. *Image-Pro* software is used to measure the thickness at a left, a left-center, a center, a right-center and a right

position for each edge locations. For each location, three measurements were recorded in the order starting with the center, left and right, respectively (Table 3.1). Figure 3.5 shows the clad thickness measurements for test sample 1. The pixel numbers are measured and then converted to actual dimension in the unit of  $\mu\text{m}$  as indicated on a linear scale on the top left corner of each figure. Since the measurements were taken on the screen using accessory software, the error resulted from the number of pixels the operator selected to represent the thickness. In this uniformity study, the uncertainty of measurement at each location is determined as being the standard deviation of three measurements.

**Figure 3. 4** Test samples and edges of the measurement of clad uniformity on a sheet

(e) Right

**Figure 3.5** Clad thickness measurements for Test sample 1. (a) Left (b) Left-Center (c) Center (d) Right-Center (e) Right

Table 3.1 summarizes the measurements of clad thickness for all the test samples. The average of three thickness measurements at each of the five locations is provided.

From Table 3.1, it can be concluded that no significant thickness difference exists for all test samples. That is, all the samples indicate very uniform distribution of the clad layer thickness before brazing. Therefore, each tested sample from the same sheet will be well represented as having identical mass of clad available to form the joint for a given, precisely tailored test samples. In the subsequent study, the clad thickness is treated to be a constant, which is equal to the average clad thickness for all the test samples,

$$\delta_{clad} = 25 \pm 1 \mu m$$

## 3.2 Experimental Procedures

### 3.2.1 Chamber Atmosphere

In order to study the kinetics of the clad spreading and joint formation during a brazing process under conditions of a Controlled Atmosphere Brazing, the OCA chamber atmosphere must be well defined. One of the essential factors of the atmosphere on the brazing process is the oxygen level in the chamber. As mentioned in Chapter 2, the purging gas sources include Nitrogen with specified

content of oxygen, i.e.,  $2\pm 2$  ppm,  $210\pm 4$  ppm,  $501\pm 10$  ppm,  $2003\pm 40$  ppm Nitrogen and 195000 - 235000 ppm air. For the convenience, all the oxygen levels are rounded to their nearest hundredth (200 ppm, 500 ppm, 2000 ppm and 200,000 ppm) for concentrations within the hot zone except for the 2 ppm case in which a 70 ppm is used due to the fact that the chamber condition can only offer  $70\pm 10$  ppm in a 2 hours time frame. The certified specifications of gas sources are provided in Appendix 1.

The oxygen level history for 70 ppm, 200 ppm, 500 ppm and 2000 ppm Nitrogen gases were recorded throughout the duration of each test as shown in Figure 3.6. The recording of the Oxygen level data starts at the time when the temperature reading is initiated (typically at  $\sim 30$  °C). The data include oxygen level corresponding to temperature history between  $\sim 577$  °C and the peak brazing temperature (heating segment), and from peak temperature to 550°C (cooling segment), see Figure 3.7. Therefore, the oxygen level history in the chamber during the whole brazing time is documented. From Figure 3.6, it can be identified that during the whole joint evolution time (the region between Start line and End line, see Figure 3.6 and Figure 3.7) the oxygen level in the chamber is under its controlled condition.

In this work, it is assumed that a 2 hour purging time is sufficient to eliminate H<sub>2</sub>O in the chamber up to the point of minimal H<sub>2</sub>O vapor impact. Therefore, the humidity in the chamber is not measured. The certified moisture level in high purity (99.999%) Nitrogen and compressed air is <3 ppm and <8 ppm, respectively provided in Appendix 1. In addition, the difference of oxygen concentration ( $\Delta O_2$ ) between specified in Appendix 1 and measured from Figure 3.6 for 200 ppm, 500 ppm and 2000 ppm dry high purity Nitrogen tests at the start of spreading is 10 ppm, 41 ppm and 3 ppm, respectively. Since the difference in oxygen level is marginal, it can be concluded that the difference in

moisture level are marginal as well. The typical dew point of air for brazing test in our lab is -54 °F after three hours purging<sup>63</sup>.

The recorded oxygen concentration data for all tests are offered in Appendix 3.

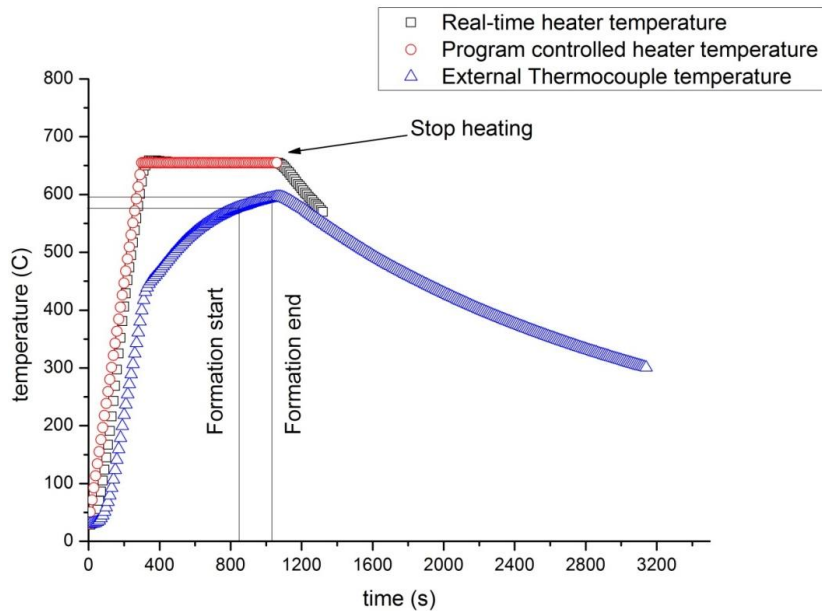

**Figure 3. 6** Oxygen level history of one test from each group (Test5\_70, Test2\_200, Test1\_500, Test9\_2000)

### 3.2.2 Temperature Profile and History

There were three temperature profiles associated with each experiment: (1) The computer program controls the heater target (setup) temperature and indicates the desired heater temperature; (2) Average two heater temperatures displayed on the controlling unit (see Figure 2.3) and; (3) External K type thermocouple temperature measurements of the substrate. These temperature profiles may be different from each other as can be clearly seen in Figure 3.7 which shows the three temperature profiles in one plot. In this study, the heater maximum target temperature is set to be 655 °C to establish a desired hot zone temperature (featuring a significant temperature delay) and to prevent the external thermocouple temperature from rising beyond  $595 \pm 5$  °C (established by a trial-and-error). The computer program is set to increase the heater temperature from 30 °C to 655 °C in 5 minutes and after that the heater keeps that temperature for a specifically defined time until the heater off button is activated. However, the actual heater coil temperature displayed on the controlling unit initially rises quite lagging behind the computer program heater temperature due to inertia but after ~200 seconds the two profiles are on top of each other (see Figure 3.7). The external thermocouple temperature profile is the one that is registering the sample temperature. This temperature was recorded during heating segment from ~ 30 °C to ~ 595°C and during cooling segment from 595 °C to 300 °C. The video recording was triggered once the external thermocouple temperature reaches 568 °C. The joining process starts in the external thermocouple temperature range of 570 °C and 580 °C. The joining processes take less than 120 seconds (or alternately 180 seconds for the higher oxygen concentrations) and once the external thermocouple temperature reaches 595 °C, the heating program was terminated. The external thermocouple temperature rises very slowly between 595 °C and 600 °C. It is ensured that at least 4 minutes long video can be recorded before the temperature decreases to below melting temperature.

The theoretical melting temperature of clad layer (Al-Si binary alloy) is known (577 °C), solidus temperature. However, melting was observed from the external thermocouple readings in the range of temperatures, i.e., between 570 °C ~ 580 °C. We were aware that the joining process is not isothermal (Figure 3.7), but the temperature deviation from the onset temperature of formation evolution is within the range of  $10 \pm 5^\circ\text{C}$ . It was assumed that this non-isothermal process has only little influence on the change of the joint formation. This may be most likely due to the fact that melting temperature of the clad alloy is not the same as for a typical Al-Si binary alloy, but also because the temperature non-uniformity of the clad layer may be present. It is assumed that the external thermocouple's measuring uncertainty is significantly smaller than the previous two reasons. The thermocouple touches the bottom of the substrate and there is some 16mm distance between the thermocouple location and the joining zone as seen in Figure 3.2. Nevertheless, since the clad substrate is very thin (0.31 mm) and aluminum alloy has a good thermal conductivity, it can be argued that the temperature distribution on the substrate should be more or less uniform. In order to verify this, a thermal Finite Element Analysis is performed using ANSYS 12.1 (Refer to Appendix 4 for details).

**Figure 3. 7** Typical temperature histories for one experiment (Test11\_2000)

The recorded external thermocouple temperature data for all tests are arranged in Appendix 5.

### 3.3 Post Experiment Processing

#### 3.3.1 Data Processing

The domain of interest is not the entire sample configuration. Rather, the domain of interest is the area shown in Figure 3.8 which covers the entire joint molten clad domain.

**Figure 3. 8** Joint domain (Test5\_70)

The horizontal and vertical lengths of the joint formation are represented by  $L_H$  and  $L_V$ , respectively (Figure 3.8). Both dimensions at left side and right side were measured.

The videos begin to be recorded at  $565 \pm 5$  °C of external thermocouple reading. The whole brazing process was recorded for more than 120 seconds for the 70ppm group and for more than 180 seconds for the 200ppm, 500ppm and 2000ppm groups to ensure that spreading ends before the recorded time was terminated. The recorded video file format type (.seq) is the one that is uniquely associated with SCA20 operating software and has 25 frames per second (FPS). The original video file was converted into an avi-type file and 120 or 180 images are extracted from that file at the rate of one image per second using Virtualdub software<sup>58</sup>. Figure 3.9 shows a sequence of joint formation images extracted

from the video at different times through the whole process. Appendix 6 offers a summary of a procedure for uncertainty of kinetics data evaluation. One sequence of extracted images for each test group can be referred to Appendix 7. The vertical and horizontal lengths are measured using the Image-Pro<sup>59</sup> as follows:

- (1) 0 ~ 30s: Formations measured at every second
- (2) 30 ~ 60s: Formations measured at every other second
- (3) 60 ~ 90s: Formations measured at every 3 second
- (4) 90 ~ 120/180s: Formations measured at every 5 second

Before each measurement, the images were calibrated by measuring the numbers of pixels of the known vertical piece thickness (0.4 mm) in Image-Pro. This allows calculating  $M$ , the length per pixel, for continuing measurement. By measuring the number of pixels of the vertical ( $N_V$ ) and horizontal ( $N_H$ ) location of the triple-line, the actual dimension can be obtained through the following equations:

$$L_V = N_V \times M$$

And,

$$L_H = N_H \times M$$

The thickness of the vertical piece was re-measured to confirm the calibration. If the re-measured thickness has a deviation of 0.01 mm from known thickness 0.4 mm, then a new  $M$  will be calculated to repeat the above procedures until convergence is reached.

A typical joint formation measurement can be seen in Figure 3.10

Figure 3. 9 Joint formation evolution. Images extracted from a video (Test5\_70)

Figure 3. 10 Measurement of joint formation of Test5\_70 at 30s

### **3.3.2 Post Processing of Brazed Samples**

One of the brazed samples from each experiment's group is randomly selected for a metallurgical study that includes primarily the inspection of the metallurgical cross section, presence of voids and/or irregularities of the cross section of a joint. Cold mounting method is used to make the samples available for subsequent cutting and polishing. Each sample was grinded with a sequence of polishing grits (#220, #500, #800 and #1200) and then polished using polishing runner (9  $\mu\text{m}$ , 3  $\mu\text{m}$  and OPU) with associated suspension and lubricant. This was followed by an etching procedure using HF + 3 ml HCl + 5 ml HNO<sub>3</sub> + 190 ml H<sub>2</sub>O. Final formation shape study was conducted with the help of Nikon EPIPHOT 300 microscopy with appropriate magnification and measurements examined using Image-Pro Software. These values are used to compare with those measured from OCA units. All the cut and polished samples are kept for the use in the subsequent study (see chapter 4).

## CHAPTER 4: RESULTS AND DISCUSSIONS

In this chapter, the results are divided into five groups in terms of oxygen concentration and plots of each test group are presented to identify the evolution phases. Subsequently, a topology study has been presented discussing clad residue and its influence on joint formation. The cross-sections profiles are examined to verify whether a 2D or 3D configuration of joint formation is present.

Refer to Appendix 8 for kinetics data for all tests from all groups.

### 4.1 70 ppm Test Group Results

Seven tests in this test group were successfully conducted with the same atmosphere conditions (70 ppm oxygen level in the chamber with 2 hour purging duration and wedge-tee sample configurations in the hot zone of the OCA units), Figure 3.1 and Figure 3.2. Figure 4.1 shows the kinetics curves of Test5\_70 and Figure 4.2 offers the average values for all the seven tests with associated error bars<sup>60</sup> (Appendix 6) in linear coordinates at both original time interval (refer to 3.3.1) and intervals of every 10 second.

Figure 4.1 and Figure 4.2 clearly indicate that both joint vertical growth ( $L_V$ ) and horizontal growth ( $L_H$ ) (Figure 3.8) reach their maximum values in  $\sim 100$  seconds for 70 ppm test group. Under the term “growth” we define the maximum reach (at an instant of time) of the triple line along the spreading direction over a respective (vertical or horizontal) surface. The triple line is, as emphasized earlier, the locus of points at which all three phases meet (1) liquid metal, (2) substrate over which the spreading takes place, and (3) gas atmosphere in contact with the previous two. This means that the whole kinetics of the spreading process takes less than 2 minutes to be fully developed.

**Figure 4. 1** Kinetic curves for Test5\_70 of 70 ppm test group

In addition, the vertical and horizontal movements are processed in a similar way, reaching average maximum values at about 0.8 mm in both cases. Gravity has been assumed to make the triple line movement in the vertical direction, against the gravity action, smaller than in the horizontal direction. However, as one can easily conclude from Figure 4.1, there is no significant difference between  $L_V$  and  $L_H$  curves, implying that the dominant force driving the flow is surface tension in both directions and thus the impact on vertical flow from gravity can be neglected (for the given joint file size considered). Moreover, it is apparent that the kinetics is symmetric since the left and right curves are on top of each other from these figures. That implies that the sample symmetry, as well as clad uniformity (discussed in 3.1.2, see Table 3.1) are clearly preserving surface tension flow of the same liquid masses on both sides of the joint zone. One should note that spreading condition on horizontal and vertical surfaces are not the same. Molten metal

“climbs” vertical surface originally solid and is exposed to possible dissolution/interaction at the liquid/solid interface only after liquid spreads over it. Horizontal surface provides liquid phase from originally solid clad that is hypoeutectic, hence melting passing through mushy zone. Still, no significant difference was identified.

No obvious difference between vertical and horizontal spreading is noted for averaged values in Figure 4.2. This clearly implies that gravity has negligible impact on the formation regardless of the increasing size of the liquid fillet.

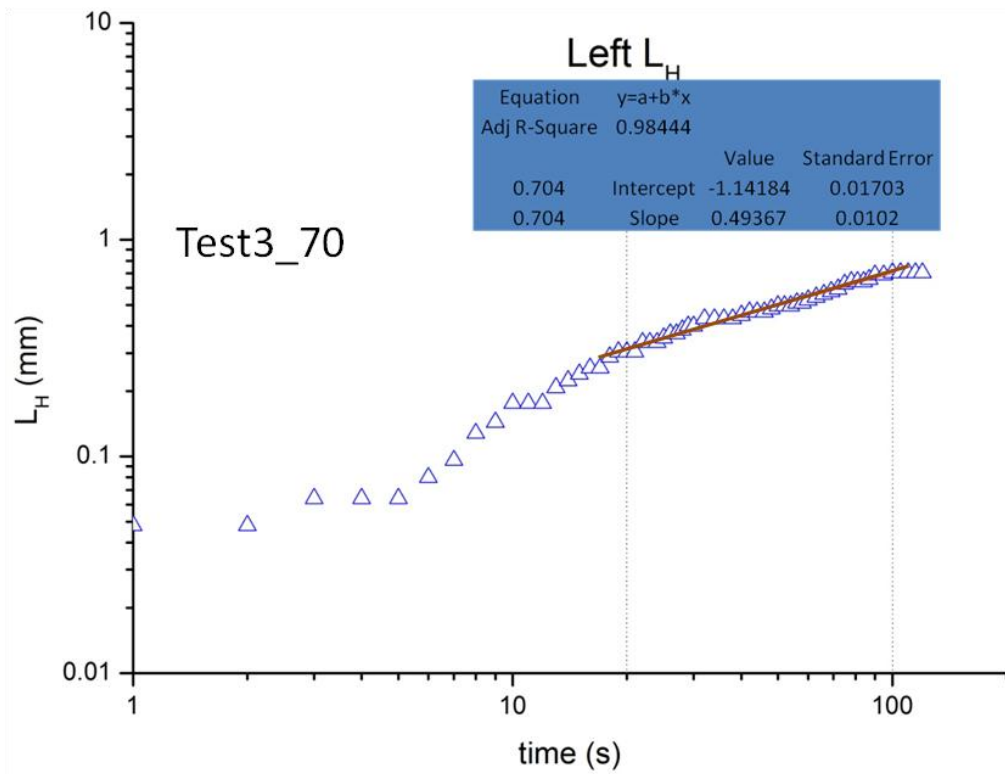

Figure 4. 2 Average kinetic data of Test1\_70 through Test7\_70 (Test4\_70 included)

The trend of these curves appears to be similar to that of a power law curve. That is, the triple line movement appears to obey the power law relationship vs. time ( $L \sim t^n$ ,  $n < 1$ ). In order to verify if a power law relationship exists between joint growth (that is, the triple line movement) and the spreading time, these curves are examined in logarithmic coordinates. If the power law is to be confirmed, the correlation must correspond to a linear data distribution in a log-log coordinate system. Figure 4.3 shows the linear curve fit for Test3\_70.

**Figure 4.3** Linear curve fit for Test3\_70. (a) Left  $L_V$  (b) Right  $L_V$  (c) Left  $L_H$  (d) Right  $L_H$

Figure 4.4 shows joint formation of all tests in logarithmic coordinates and Figure 4.5 presents the average joint formation of these tests in logarithmic coordinates. The power values ( $n$ ) for all tests in 70 ppm test group are summarized in Table 4.1. (The uncertainty for each column is the sum of system uncertainty (STD) using ORIGINPRO 8<sup>61</sup> and standard deviation resulting from number of tests in the test group.)

From these figures, the development of formation can be divided into 3 phases:

(1) Initial Phase from 0 to 20s:

This phase indicates a larger scatter in the logarithmic representation. This is due to primarily:

- a) the nature of the logarithmic coordinates that lead to the fine data density at first few seconds presented over large domain;
- b) most likely inertia influence, as indicated in Ref. 7 (Note: an impact of gravity most likely would not be present because at initial stages the Bond number, a dimensionless number that decides the importance of surface tension force compared to gravity force. Assuming the density and surface tension of molten

clad keep constant regardless of spreading time, at the start of joining process, the Bond number is small due to small joint area and later the number becomes larger due to the increase of joint. The Bond number that is associated with the equilibrium state is estimated to be 0.006 knowing that the surface tension, density of clad and joint cross section area being 849.1mN/m, 2407.2kg/m<sup>3</sup> and 0.2146 mm<sup>2</sup>, respectively<sup>64</sup>. However, it is shown that gravity can be neglected on vertical evolution of joint formation and the smaller Bo number indicates less influence of the gravity.

c) measurement uncertainty results from a very small pixel changes and difficult to identify between two subsequent frames;

d) the presence of an initial small but not necessarily negligible clearance between vertical piece and substrate.

(2) 0.525 Power Law Phase from 20 to 100s:

This stage is dominated by capillary force which drives the spreading in both vertical and horizontal directions and a less dominant impact of viscous force. Joint formation in this stage is directly proportional to 0.525 (an average excluding the outlier, Test4\_70, see Table 4.1) power of spreading time. The relationship between formation and spreading time is close to the Washburn type ( $L \sim t^{1/2}$ ).<sup>6</sup> Note that surface of the sample is assumed to be smooth enough that the roughness was not considered in this study although we are aware of the impact from surface roughness on the interfacial energy between solid phase and liquid phase (not dominant).

(3) Asymptotic Phase from 100 to 120s:

The kinetics curves become flat and no significant joint evolution development is noticed beyond ~100s indicating the balance between all acting forces including the viscous force.

To eliminate the influence of individual test joint lengths so the trend can be further evaluated, both vertical and horizontal lengths are scaled by their

respective maximum length, the corresponding vertical or horizontal length at the end of tests, maximum values from test to test, see Appendix 8, such that:

$$0 \leq L_V/L_{VM} \leq 1 \text{ and,}$$

$$0 \leq L_H/L_{HM} \leq 1$$

**Figure 4.** 4 Joint formation of Test1\_70 to Test7\_70 in Logarithmic Coordinates

Figure 4.6 shows normalized formations for all tests and Figure 4.7 shows average normalized length in logarithmic coordinates. The three stages of joint development can be identified. It is hypothesized that the discrepancies between tests are probably influenced by a slight initial condition difference, such as atmosphere condition and sample location within the hot zone. Nevertheless, the kinetic mechanism can be represented by unique model.

**Figure 4. 5** Average joint formation kinetics curves of Test1\_70 to Test7\_70 in Logarithmic Coordinates

From Figure 4.4 and Figure 4.6, all the tests data agree well as far as the power law validity is concerned in Phase 2 and 3 except Test4\_70, regardless the normalization. From Table 4.1, it is noted that the evolution rate of Test4\_70 is faster than others. The reason is not known and must be investigated; still we decided to include this data set as an artifact of measurement. The overall slope representing joint evolution in phase 2 without the influence of Test4\_40 is  $0.525 \pm 0.082$ .

**Figure 4. 6 Normalized joint formations in logarithmic coordinates**

**Figure 4. 7 Average normalized joint formations in logarithmic coordinates**

A brazed sample from Test5\_70 was randomly selected for further joint cross-section analysis. The distance between the brazing sheet lower surface and the clad/core interface is investigated for both pre-brazed and brazed samples to identify the by the liquid penetration caused movement of the interface (a partial aluminum core erosion during brazing<sup>50,62</sup>). Due to the nature of the brazing joining process, brazing with a brazing sheet (a horizontal mating surface in our tests) leads to clad melting in situ and surface tension driven flow of the formed liquid into the joint, leaving a residual clad. Any remaining liquid clad is re-solidified in situ, see the previous work of the UK Brazing laboratory.<sup>50</sup> The residual clad thickness is examined by using Image-Pro in order to establish the amount of clad that forms the joint. The measurement of the residue thickness is executed as follows: [for a more detailed discussion of this issue, see Reference 36.]

- (1) The distance between the brazing sheet lower surface and the interface in the pre-brazed sample is measured,  $\delta_{c,pb}$ .
- (2) The distance between the brazing sheet lower surface and the interface in the brazed sample is measured,  $\delta_{c,b}$ .
- (3) The comparison between the value determined in (1) with that determined in (2) is performed to examine whether the core/clad interface has shifted.

$$\delta_{c,pb} > or < \delta_{c,b}$$

- (4) The thickness of a brazed sample is measured,  $\delta_b$ .
- (5) The difference between the values in (4) and (2),  $\delta_r = \delta_b - \delta_{c,b}$ , leads to the clad residue thickness [if there is no significant difference between the value in (2) and (1)].
- (6) The difference between the verified uniform clad thickness,  $\delta_{clad}$ , in 3.1.2 (Table 3.1) and the value in (5) leads to the clad thickness that is available to form the joint.

$$\delta_{joint} = \delta_{clad} - \delta_r$$

Figure 4.8 shows the characteristic layers designations of pre-brazed and brazed sample.

The distances between the brazing sheet lower surface and interface from the clad uniformity test sample 1 (Table 3.1) and that from Test5\_70 can be seen in Figure 4.9.

All the results are based on the measured pixel number. See the top left corner of the pictures for the linear physical scale.

**Figure 4. 8** Designation of brazing sample

**Figure 4. 9** Measurement of the distance between the brazing sheet lower surface and the interface in a pre-brazed and brazed samples near a joint

The average distance for a pre-brazed and 70 ppm tests brazed sample is  $287 \pm 1$  μm and  $285 \pm 1$  μm based on three measurements for each sample as can be seen in Figure 4.9, respectively. The difference is 2 μm with the uncertainty of  $\pm 2$  μm. Hence, it may be stated that there is in average no significant movement of interface. Therefore, the interface is assumed to be not significantly altered.

The brazed substrate cross-section (including the clad layer) is presented again in Figure 4.10, with markings indicating measurements of the substrate thickness.

**Figure 4.10** Measurement of a brazed substrate thickness

The average brazed substrate thickness is  $300 \pm 5 \mu\text{m}$ . Therefore, the residual thickness is  $(300 \pm 5) - (285 \pm 1) = 15 \pm 6 \mu\text{m}$ . Then the clad thickness that forms the joint is the difference of pre-brazed clad thickness from clad uniformity test  $25 \pm 1 \mu\text{m}$  and the residual thickness  $15 \pm 6 \mu\text{m}$ ,  $10 \pm 7 \mu\text{m}$ .

Table 4.2 shows the results from each step mentioned earlier.

**Table 4.2** Summarized measurements for residue thickness of Test5\_70

70 ppm	Measurement ( $\mu\text{m}$ )	Comment	Note
step1	$287 \pm 1$	Distance between the brazing sheet lower surface and the interface in the pre-brazed sample	Assumed to be the same for all tests
step2	$285 \pm 1$	Distance between the brazing sheet lower surface and the interface in the brazed sample	
step3	$2 \pm 2$	Absolute difference between measurements in step 1 and step 2	Interface assumed intact
step4	$300 \pm 5$	The thickness of a brazed sample	
step5	$15 \pm 6$	Clad residue thickness	
step6	$10 \pm 7$	Clad thickness that is available to form the joint	

Figure 4.11 shows the core dissolution due to silicon diffusion across the interface in particular within the location of joint formation. Figure 4.12 provides three cross-section profiles at  $z=1.5 \text{ mm}$ ,  $7.5 \text{ mm}$  and  $13.5 \text{ mm}$  along the axial direction of the joint fillet, see Figure 4.8 for axes markings.

**Figure 4. 11** Measurements of core dissolution for Test5\_70

It is noted that the clearance between the substrate and vertical piece is fully filled with clad and no voids are visible. Aside from the clearance, at the left and right sides, the maximum dissolution depths of the horizontal piece from the original surface are  $45 \pm 1 \mu\text{m}$  and  $30 \pm 1 \mu\text{m}$ , respectively. At the left and right sides, the maximum diffusion depths of the vertical piece are  $76 \pm 1 \mu\text{m}$  and  $53 \pm 1 \mu\text{m}$ , respectively. It appears from Figure 4.11 that the average dissolution depth of vertical piece is larger than that of horizontal piece locally partially due to the fact that the clad layer originally existed on the substrate and solid state diffusion at the interface may be different, and partially due to the fact that molten clad has “climbed” the vertical piece over time so that dissolution close to the substrate is much more pronounced than away from the brazing sheet surface.

Note that all the auxiliary lines in Figures 4.12 are used for assisting the measurements of the triple line location.

The vertical and horizontal fillet joint’s lengths measured at 3 locations are summarized in Table 4.3:

**Table 4.3** Measured fillet formations at 3 locations along z axis (Figure 3.8 and Figure 4.8) for Test5\_70 (mm)

70ppm	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.883	0.912	0.939	0.911	0.028
Left LH	0.874	0.894	0.848	0.872	0.023
Right Lv	0.898	0.958	0.920	0.925	0.030
Right LH	0.821	0.918	0.882	0.874	0.049

**Figure 4. 12** Measurements of formation at 3 locations along the z axis for Test5\_70

Hence, it can be validated that a 2-D joint formation under 70 ppm oxygen level condition is confirmed to a large degree. So, we postulate that the depth variation has negligible effect on the fillet cross-section profile. This statement is of particular importance for the level of optical sharpness of the fillet profile (a free surface of the fillet formed over time) that is reduced significantly if a cross-section of a joint changes along the z axis, Figure 4.8.

The equilibrium joint formations of Test5\_70 measured using OCA units are:  
 Left  $L_V = 0.816$  mm, Left  $L_H = 0.815$  mm, Right  $L_V = 0.831$  mm, Right  $L_H = 0.800$  mm.  
 (Appendix 8)

Since the camera of the OCA units is focused on the cross section that is at 0 mm along the z axis (i.e., closest to the observer) and the cross section at  $z=1.5$  mm is close to the one at  $z=0$  mm, the relative deviations for  $L_V$  and  $L_H$  at both sides are based on measurements at 1.5 mm from Table 4.1. (The deviation between OCA and micrographs measurements of the L value is determined as a relative difference between these values,  $L_{OCA}$  from Appendix 8 and  $L_{Micro}$  from Table 4.3)

$$\text{Left:} \quad \%L_V = \left| \frac{0.816 - 0.883}{0.883} \right| = 8\%, \quad \%L_H = \left| \frac{0.800 - 0.874}{0.874} \right| = 8\%$$

$$\text{Right:} \quad \%L_V = \left| \frac{0.831 - 0.898}{0.898} \right| = 9\%, \quad \%L_H = \left| \frac{0.800 - 0.821}{0.821} \right| = 3\%$$

These deviations are due to the following reasons:

- (1) The shrinkage (liquid/solid) is not taken into consideration.
- (2) The position of the sample in the chamber is not perfectly vertical or horizontal ( $90^\circ \pm 1.5^\circ$  between mating surfaces, see 3.1.1);
- (3) The cross section measured using OCA (at  $z=0$  mm) is not exactly the one polished (at  $z=1.5$  mm)
- (4) Sample configuration (See below for explanation)

The fillet formation's topographical metrics values, measured at the brazing sheet edge using OCA are smaller than those measured at three different locations along z axis. This implies that the sample configuration (See Figure 3.1 and Figure 3.2) has

an influence on the joint formation (though small) at the edge area under 70 ppm condition.

## 4.2 200 ppm Group Results

Three tests in this group were performed with the same mating surfaces' configuration as for the 70 ppm group, but with a different oxygen level in the hot zone chamber, i.e., a high purity nitrogen with 200 ppm of oxygen. The kinetics data of the Test2\_200 is plotted in Figure 4.13. Figure 4.14 shows the average triple line location with their associated error bars for all the three tests.

**Figure 4. 13** Kinetics plot of Test2\_200

Again, the maximum vertical and horizontal positions (the asymptotic location) of the triple line under 200 ppm condition are about 0.8 mm, which are virtually the same as under 70 ppm condition. However, under 200 ppm condition, it can be clearly observed that it takes ~160 seconds for the formation to be completed, 1

minute longer than under 70 ppm condition. This is, we hypothesize, due to the worse atmosphere condition (because all the other conditions were identical, i.e. uniform clad and temperature conditions). In addition, the individual trend of vertical and horizontal spreading is similar (Figure 4.13 and Figure 4.14) implying the gravity influence is insignificant.

**Figure 4. 14** Average kinetics of all tests in 200 ppm group

**Figure 4. 15** Vertical triple line location evolution of Test1\_200

It may be noted that in the Test1\_200 (Figure 4.15) database an asymmetric spreading occurs along vertical direction leading to the two curves in the top left corner of Figure 4.14 not on top of each other after ~120 seconds. More tests in this group need to be performed to confirm whether slightly asymmetric spreading in vertical direction is accidentally random artifact or a consequence of the particular influential factor. However, regardless of this artifact, it is concluded that spreading under 200 ppm condition leads to the symmetric joint formation.

To investigate whether a power law relation between joint formation and spreading time exists under 200 ppm condition, the kinetic data were analyzed in logarithmic coordinates. Figure 4.16 shows the linear curve fit for Test2\_200 and Figure 4.17 and Figure 4.18 present triple line location development for all the tests in 200 ppm test group, individual tests locations and average values, respectively. The power values ( $n$ ) for Test1\_200 through Test3\_200 are summarized in Table 4.4.

**Table 4. 4** Summarized power values for all the tests in 200 ppm test group

**Figure 4. 17** Joint formations of Test1\_200 to Test3\_200 in Logarithmic coordinates

**Figure 4.18** Average Joint formation of Test1\_200 to Test3\_200 in logarithmic coordinates

From these figures, the development of formation under 200 ppm condition can also be divided into 3 phases as those for the 70 ppm group:

(1) Initial phase from 0 to 15s:

It is noted that compared to the same phase under the 70 ppm condition (20 seconds), the duration of this phase under 200 ppm condition (15 seconds) is 5 seconds shorter.

(2) 0.525 Power Law Phase from 15 to 160s:

The relationship between formation and spreading time is close to Washburn model ( $L \sim t^{1/2}$ ). The power value (0.525) in this phase under 200 ppm condition is roughly the same as that under 70 ppm condition, without the influence of an outlier of Test4\_70 ( the average slope under 70 ppm condition is 0.525 , the same as that under 200 ppm condition!)

(3) Asymptotic phase from 160 to 180s.

Again, no obvious differences between vertical and horizontal triple line locations are noted (Figure 4.13 and Figure 4.14) in this phase. This implies that gravity has negligible impact on the formation under 200 ppm condition.

Figure 4.19 shows normalized formations for all tests and Figure 4.20 shows average normalized triple line locations in logarithmic coordinates under 200 ppm condition.

A brazed sample from Test2\_200 was randomly selected for further analysis as described for a corresponding one under 70 ppm condition. Figure 4.21 shows the measurement of distance between the interface and bottom face of Test2\_200.

The brazed substrate thickness (including the clad layer) is presented in Figure 4.22. Table 4.5 shows the measurements results from each step similar as those in Table 4.2.

200 ppm	Measurement ( $\mu\text{m}$ )	Comment	Note
step1	$287 \pm 1$	Distance between the brazing sheet lower surface and the interface in the pre-brazed sample	Assumed to be the same for all tests
step2	$288 \pm 1$	Distance between the brazing sheet lower surface and the interface in the brazed sample	
step3	$1 \pm 2$	Absolute difference between measurements in step 1 and step 2	Interface assumed intact
step4	$300 \pm 1$	The thickness of a brazed sample	
step5	$12 \pm 2$	Clad residue thickness	
step6	$13 \pm 3$	Clad thickness that is available to form the joint	

Figure 4.23 shows the minor core dissolution due to silicon diffusion in the joint over horizontal substrate for joint formation in brazed Test2\_200. Note that the dissolution is significant for the vertical surface.

**Figure 4. 23** Measurements of core dissolution (Test2\_200)

The clearance between the substrate and vertical piece is fully filled with clad. At the left and right sides, the maximum dissolution depths of the horizontal piece from the original surface are  $27 \pm 1 \mu\text{m}$  and  $23 \pm 1 \mu\text{m}$ , respectively. The maximum diffusion depths of the vertical piece are sizably larger, i.e.,  $53 \pm 1 \mu\text{m}$  and  $41 \pm 1 \mu\text{m}$ , respectively.

Figure 4.24 provides three cross-section profiles at  $z=1.5 \text{ mm}$ ,  $7.5 \text{ mm}$  and  $13.5 \text{ mm}$  along the  $z$  axis of the joint fillet (Figure 4.8) for Test2\_200.

The vertical and horizontal lengths measured at 3 locations are summarized in Table 4.6.

Hence, it can be validated that a 2-D joint formation under 200 ppm oxygen level condition is also preserved. The location along the  $z$  axis (along the joint fillet) has minimal effect on the cross-section size of the fillet.

**Figure 4.** 24 Measurements of formation at 3 locations along the z axis (Test2\_200)

**Table 4.6** Measured fillet formations at 3 locations along the z axis (mm)

200ppm	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.944	0.983	0.971	0.966	0.020
Left LH	0.988	1.036	0.980	1.001	0.030
Right Lv	0.926	0.956	0.952	0.945	0.016
Right LH	0.988	0.962	0.953	0.968	0.018

The equilibrium joint fillet formations of Test2\_200 measured by OCA units are:

Left  $L_V = 0.800$  mm, Left  $L_H = 0.781$  mm, Right  $L_V = 0.800$  mm, Right  $L_H = 0.819$  mm.  
(Appendix 8)

The relative deviations in measurements under the 200 ppm condition are:

$$\text{Left:} \quad \%L_V = \left| \frac{0.800 - 0.944}{0.944} \right| = 15\%, \quad \%L_H = \left| \frac{0.781 - 0.988}{0.988} \right| = 21\%$$

$$\text{Right:} \quad \%L_V = \left| \frac{0.800 - 0.926}{0.926} \right| = 14\%, \quad \%L_H = \left| \frac{0.819 - 0.988}{0.988} \right| = 17\%$$

The relative deviations are larger compared to those under the 70 ppm condition. Hence, the edge influence may be considered. It appears that a deterioration of the conditions for facilitating clad flow may offer less liquid into the zone of the joint that receives liquid only from one side (along the joint formation).

### 4.3 500 ppm Group Results

Three experiments in this group were performed with the same configurations as for the 70 ppm and 200 ppm groups but with a different oxygen level in the chamber (at the level of 500 ppm). The kinetics data of Test2\_500 is plotted in Figure 4.25. Figure 4.26 shows the average lengths with their associated error bars for all the three tests.

Figure 4. 25 Kinetics plot of Test2\_500

Under 500 ppm condition, it takes ~160 seconds for the joint formation to evolve into the ultimate equilibrium state, virtually the same duration as under 200 ppm condition. It may be speculated that 200 ppm and 500 ppm are still too close to each other to cause a significant change in the triple line evolution, as opposed to 70 ppm case. In addition, it can be clearly seen in Figure 4.25 and Figure 4.26 that the joining process features filling the joint fillet differently at the two sides at the

vertical mating surface, i.e., the joint is asymmetric (a significant triple line variation on left vs. right side, both along the vertical and the horizontal directions).

**Figure 4. 26** Average kinetic data of all tests in the 500 ppm group

As indicated, both 200 ppm and 500 ppm hot zone chamber conditions result in a 160 seconds of the development of the joint formation, sizably longer than what is observed under 70 ppm condition. So, as hypothesized earlier, it is expected that a

worse atmosphere condition brings an impact on the joint formation that results in a larger joint evolution time. In support of that hypothesis, it is indicated that 500 ppm condition not only leads to a longer formation development but also results to an asymmetric joint formation. To investigate whether a power law relation between joint formation and spreading time exists under 500 ppm condition, kinetic data were analyzed in logarithmic coordinates. Figure 4.27 shows the linear curve fit for Test2\_500 within the surface tension-viscosity phase, and Figure 4.28 and Figure 4.29 provide the triple line location development for all the tests in 500 ppm test group. The power values (n) for Test1\_500 through Test3\_500 are summarized in Table 4.7.

**Table 4.7** Summarized power values for all the tests in 500 ppm test group

500 ppm LLv	Power (20s - 160s)	500 ppm RLv	Power (20s - 160s)	500 ppm LLH	Power (20s - 160s)	500 ppm RLH	Power (20s - 160s)

**Figure 4. 28** Joint formation of Test1\_500 to Test3\_500 in logarithmic coordinates

**Figure 4. 29** Average Joint formation of Test1\_500 to Test3\_500 in logarithmic coordinates

From these figures, the development of the joint formation under 500 ppm (interpreted through the triple line movement) can still be divided into 3 stages:

- (1) Initial Phase from 0 to 20s.
- (2) 0.463 Power Law Phase from 20 to 160s.

The power law exponent value in this phase is smaller than that under 70 ppm and 200 ppm conditions indicating that a worse atmosphere condition results in slower formation growth rate. Hence, with the increase of oxygen level from 200 ppm to 500 ppm, it is hypothesized this leads to a change of the impact of the surface tension/capillary force and viscous force.

- (3) Asymptotic Phase from 160 to 180s.

The curves become flat and no significant joint development is noticed beyond 160s indicating the full balance between capillary force, viscous force and possibly gravity.

Figure 4.30 shows normalized formations for all tests and Figure 4.31 shows average normalized length in logarithmic coordinates under 500 ppm condition.

**Figure 4. 30** Normalized joint formation of Test1\_500 to Test3\_500 in logarithmic coordinates

**Figure 4.31** Average normalized formation of Test1\_500 to Test3\_500 in logarithmic coordinates

Brazed sample of Test2\_500 was randomly selected for further analysis as described for that under 70 ppm and 200 ppm conditions. Figure 4.32 shows the measurements of the distance between the interface and the lower surface of the brazing sheet.

**Figure 4.32** Measurement of the distance between the brazing sheet lower surface and the clad/core interface of a brazed sample (Test2\_500) near the joint area (to the right)

The brazed substrate thickness is examined in Figure 4.33. Table 4.8 shows the measurements results from each step similar as those in Table 4.2 and Table 4.5.

**Figure 4. 33** Measurement of the brazed sample thickness (Test2\_500)

**Table 4.8** Summarized measurements for residue thickness study for Test2\_500

500 ppm	Measurement ( $\mu\text{m}$ )	Comment	Note
step1	$287 \pm 1$	Distance between the brazing sheet lower surface and the interface in the pre-brazed sample	Assumed to be the same for all tests
step2	$288 \pm 1$	Distance between the brazing sheet lower surface and the interface in the brazed sample	
step3	$1 \pm 2$	Absolute difference between measurements in step 1 and step 2	Interface assumed intact
step4	$300 \pm 2$	The thickness of a brazed sample	
step5	$12 \pm 3$	Clad residue thickness	
step6	$13 \pm 4$	Clad thickness that is available to form the joint	

Figure 4.34 shows the core dissolution due to silicon diffusion in the joint formation in Test2\_500.

**Figure 4. 34** Measurements of core dissolution (Test2\_500)

The clearance between the horizontal substrate and vertical piece is completely filled with re-solidified clad. At the left and right sides, the maximum dissolution depths of the horizontal piece from the original surface are  $26 \pm 1 \mu\text{m}$  and  $17 \pm 1 \mu\text{m}$ , respectively. The maximum diffusion depths of the vertical piece are  $33 \pm 1 \mu\text{m}$  and  $30 \pm 1 \mu\text{m}$ , respectively.

Figure 4.35 provides cross-section #1, cross-section #2 and cross-section #3 profiles at  $z=1.5 \text{ mm}$ ,  $z=7.5 \text{ mm}$  and  $z=13.5 \text{ mm}$ , respectively, along the  $z$  axis. The vertical and horizontal triple line locations measured at 3 cross-section profiles are summarized in Table 4.9.

It is clearly observed that along the depth direction  $L_V$  increases progressively and  $L_H$  reaches its maximum value at the center (7.5 mm). Based on the average value in Table 4.3 and Table 4.6, the standard deviations of all formations are much bigger ( $>0.08 \text{ mm}$ ) than those under 70 ppm and 200 ppm conditions. This implies that a 2-D configuration of joint formation can be questionable under 500 ppm condition. Clearly, the deterioration of the conditions causes non-uniform distribution of the clad flow. This phenomenon required further systematic study.

**Table 4.9** Measured fillet formations of Test2\_500 at 3 locations along the  $z$  axis (mm)

500ppm	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left $L_V$	0.768	0.888	0.923	0.860	0.081
Left $L_H$	0.817	1.026	0.939	0.927	0.105
Right $L_V$	0.662	0.889	0.920	0.824	0.141
Right $L_H$	0.758	1.008	0.974	0.913	0.136

The equilibrium joint formations of Test2\_500 measured using OCA units are:  
 Left  $L_V = 0.607 \text{ mm}$ , Left  $L_H = 0.637 \text{ mm}$ , Right  $L_V = 0.785 \text{ mm}$ , Right  $L_H = 0.681 \text{ mm}$ .  
 (Appendix 8)

The relative deviations for  $L_V$  and  $L_H$  at both sides are:

$$\text{Left: } \%L_V = \left| \frac{0.607-0.768}{0.768} \right| = 21\%, \quad \%L_H = \left| \frac{0.637-0.817}{0.817} \right| = 22\%$$

Right:  $\%L_V = \left| \frac{0.785 - 0.662}{0.662} \right| = 19\%$ ,  $\%L_H = \left| \frac{0.681 - 0.758}{0.758} \right| = 10\%$

The relative deviations are quite larger compared to those under the 70 ppm and 200 ppm conditions. This is because of both the combination of edge influence and non-uniformity joint formation along the z axis.

Figure 4. 35 Measurements of formation at 3 locations along the depth direction

#### 4.4 2000 ppm Group Results

In order to explore a more severe deterioration of the background atmosphere, two additional series of tests had been executed. The first one involves a 400% increase in the oxygen concentration vs. the previous one, i.e., 2000 ppm vs. 500 ppm Oxygen. This series will be reviewed in this section. The final series refers to an air atmosphere conditions which has to illustrate an ultimate deterioration of up to 200000 ppm of Oxygen, and will be reviewed in the next section, 4.5.

11 tests were performed to investigate the kinetics of the triple line movement under the 2000 ppm Oxygen concentration condition. These tests can be divided into 4 groups, based on sample configurations and atmosphere condition.

##### 4.4.1 The standard configuration & modified oxygen conditions:

7 tests were conducted with the same sample configuration used for tests under 70 ppm, 200 ppm and 500 ppm conditions.

Figure 4.36 shows the representative joint evolution (Test9\_2000) for 3 minutes of recording time.

Figure 4. 36 Joint formation development of Test9\_2000

It must be clear, after inspection of the sequence of images given in Figure 4.36 that the equilibrium envelopes of the growing fillet are becoming fuzzy and out of focus (what had not necessarily been a consequence of the out of focus imaging at the selected initial location). It can be clearly observed that after 30 seconds the area around vertical piece represented by shadow becomes darker and bigger and the cross-section profiles become blurry. This makes it impossible to reliably measure joint formations during the whole evolution time in the OCA. As mentioned earlier, the cross-section of T-joint seen in the OCA is the edge cross-section (at  $z=0$  mm) along the joint fillet direction (Figure 4.8). In addition, the dimensions of  $L_V$  and  $L_H$  for that cross-section between 30s and 60s hardly change according to this observation (Figure 4.36). Therefore, this indicates that the formation development along the depth direction is not uniform. The change of shade level and dimension of shadows is due to the growth of formation at locations along the depth direction. The non-uniformity of joint development was confirmed at  $z=1.5$  mm, 7.5 mm and 13.5 mm along the joint fillet direction through the *posteriori* evaluation of the re-solidified fillets formations (Figure 4.37).

The vertical and horizontal triple line locations measured at 3 locations are summarized in Table 4.10.

It is noted from Figure 4.37 that the joint formation is asymmetric under the condition of the oxygen level at 2000 ppm. Furthermore, from Table 4.10 one can notice that the joint formation (fillet) increases along the axial direction of the joint at an advanced “depth” location. Note that the standard deviations of the triple line locations are sizably larger when compared with those under 70 ppm, 200 ppm and 500 ppm conditions. Hence, it is relatively established that the non-uniformity of the joint formation becomes evident with an increase of oxygen level in the chamber due to the non-uniformity of molten clad flow into the joint (most likely due to an increased impact of oxidation during the joint formation at high Oxygen concentrations).

**Table 4.10** Measured fillet formations at 3 locations along the depth direction (mm)

2000ppm	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.256	0.809	0.917	0.661	0.355
Left LH	0.258	1.055	1.197	0.837	0.506
Right Lv	0.138	0.885	1.123	0.715	0.514
Right LH	0.218	0.967	1.306	0.830	0.557

**Figure 4. 37** Joint formation of Test9\_2000 at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction

#### 4.4.2 Prolonged purging duration

To explore whether the residue of the hot zone atmosphere prior to test execution may impact the experimental evaluations, one test was conducted with the same sample configuration as that in 4.4.1 but with an increased purging time, i.e., 4 hours and 15 minutes of purging of the 2000 ppm Nitrogen (Appendix 1).

Figure 4.38 shows the joint evolution of Test11\_2000 for 3 minutes of recording time. The non-uniformity of the joint formation still exists; even though the purging duration was increased to more than 4 hours. Figure 4.39 shows the joint formations at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction.

The vertical and horizontal triple line locations measured at 3 locations are summarized in Table 4.11.

**Table 4.11** Measured fillet formations from test with prolonged purging condition at 3 locations along the depth direction (mm), 2000 ppm

4.25 hr purging	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.359	0.888	1.027	0.758	0.352
Left LH	0.426	0.824	1.156	0.802	0.365
Right Lv	0.333	0.782	1.094	0.736	0.383
Right LH	0.412	0.936	1.224	0.857	0.412

The non-uniformity and an asymmetry of the joint formation were still observed in this test under a prolonged purging Nitrogen condition. It can be concluded that the non-uniformity of the joint formation under 2000 ppm would not be impacted by the purging duration. Hence, a 2 hour purging of Nitrogen is considered as being sufficient to reach specified condition.

**Figure 4. 38** Joint formation development of Test11\_2000 under prolonged purging condition. The fuzziness of the fillet free surface is apparent.

**Figure 4. 39** Joint formation of Test11\_2000 at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction

### 4.4.3 “Inverse” configuration

In order to explore whether the sample configuration/orientation within the hot zone has an impact, 2 tests were performed under an “inverse” sample configuration depicted in Figure 4.40.

**Figure 4. 40** Normal Configuration VS Inverse Configuration in top view

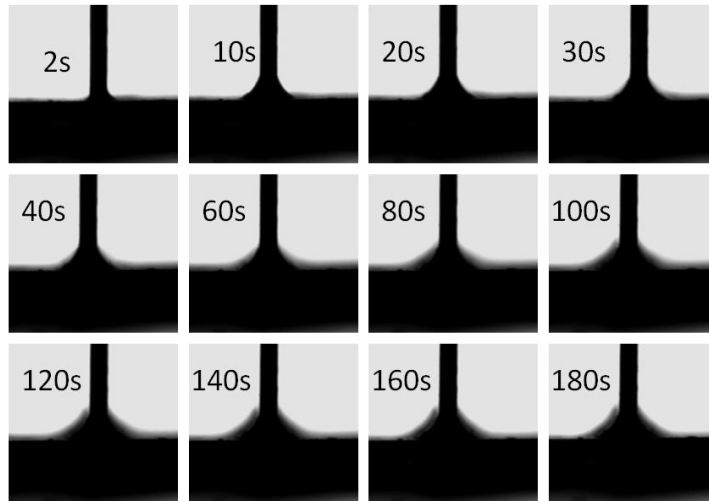

Figure 4.41 shows the joint evolution of Test4\_2000 for 3 minutes of recording time with the “inverse” configuration. Figure 4.42 shows the joint formations at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction.

The vertical and horizontal lengths measured at 3 locations are summarized in Table 4.12.

**Table 4.12** Measured fillet formations from test with an inverse configuration at 3 locations along the joint fillet direction (mm), 2000 ppm

Inverse Configuration	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.633	0.915	0.868	0.805	0.151
Left LH	0.691	0.930	0.995	0.872	0.160
Right Lv	0.747	0.921	0.852	0.840	0.088
Right LH	0.712	0.882	0.826	0.807	0.087

It can be seen that under “inverse” configuration the asymmetry and non-uniformity still exist but are better mitigated compared with the previous configuration. Further investigation needs to be conducted.

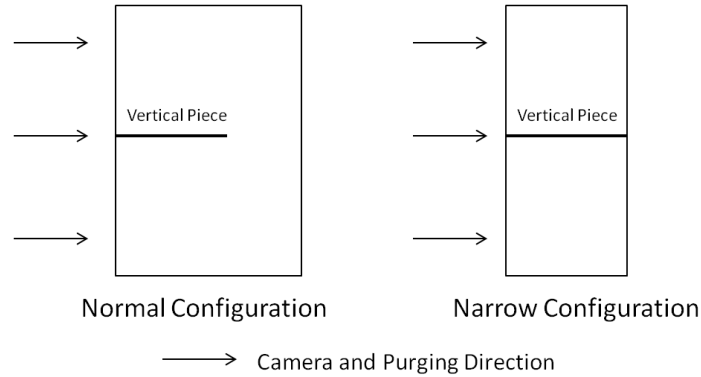

**Figure 4. 41** Joint formation development of Test4\_2000 under inverse configuration

**Figure 4. 42** Joint formation of Test4\_2000 at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction

#### 4.4.4 “Narrow” configuration

Further sample configuration has been considered. Namely, 2 tests were performed on samples with a so called “narrow” sample configuration. The narrow sample configuration is presented in Figure 4.43.

**Figure 4. 43** Normal Configuration VS Narrow Configuration in top view

Figure 4.44 shows the joint evolution of Test8\_2000 for 3 minutes of recording time. Figure 4.45 shows the joint formations at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction for that test.

The vertical and horizontal lengths measured at 3 locations are summarized in Table 4.13.

**Table 4.13** Measured fillet formations from test with narrow configuration at 3 locations along the joint fillet direction (mm), 2000 ppm

Narrow Configuration	1.5 mm	7.5 mm	13.5 mm	Average	Std
Left Lv	0.523	0.858	0.853	0.745	0.192
Left LH	0.598	0.838	0.894	0.777	0.157
Right Lv	0.370	0.845	0.852	0.689	0.276
Right LH	0.573	0.873	0.891	0.779	0.179

As it can be seen (Figure 4.43 and Figure 4.44 and Table 4.13), under the narrow configuration the asymmetry and non-uniformity still exist but are a bit better mitigated when compared with the original configuration. It may be hypothesized that this is due to the geometric symmetry of the sample configuration. The center line of the substrate is coincident with the center line of the vertical piece hence

resulting in more or less uniform formation along the depth direction. Further investigation needs to be designed to verify this.

Figure 4. 44 Joint formation development of Test8\_2000 under narrow configuration

Figure 4. 45 Joint formation of Test8\_2000 at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction

#### 4.5 200000 ppm (Compressed Air) Group Results

Finally, to consider a case of an ultimately poor background atmosphere conditions, three tests were performed under the 200000 ppm (compressed air) condition, with all the other conditions unchanged. The video recording time was increased to 7 minutes corresponding to thermocouple temperature change in the range of 569 °C ~ 605 °C, in order to examine whether a joint formation takes place at all. Joint formations were not observed in all three tests.

Figure 4.46 shows the three cross-sections of samples' mating surfaces at 1.5 mm, 7.5 mm and 13.5 mm along the joint fillet direction.

**Figure 4. 46** Three cross-section profiles along the joint fillet direction of Test2\_CA

It is clearly seen that the joint zone is not formed and that the clearance between vertical piece and substrate at 7.5 mm and 13.5 mm is not filled with the re-solidified clad. At 1.5 mm location, a small portion of the gap is filled. Note that some melting of the clad and its re-solidification in form of the primarily alpha phase in the joint zone are apparent. Some re-solidified eutectic phase is accumulated away from the vertical mating surface (see in particular the 13.5 mm cross-section), but this liquid was not able to flow into the joint. Therefore, it is concluded that brazing cannot join AA3003 vertical piece to the horizontal substrate with this clad material under air/atmosphere conditions. Since joint formation was observed under 2000 ppm condition, there must be a threshold between 2000 ppm and 200000 ppm under which joint formation fails to occur while keeping other conditions unchanged. This threshold has been under consideration by another project currently under way in the UK brazing laboratory<sup>65</sup>.

#### 4.6 Summary Comparisons of the Kinetics Results for Different Background Atmosphere Conditions

The joint formation non-uniformity was not negligible under 2000 ppm condition, and no joint formation was observed under the atmosphere of 200000 ppm Oxygen content (Air). So, the kinetics of the triple line movement comparisons was made for 70 ppm, 200 ppm and 500 ppm tests only.

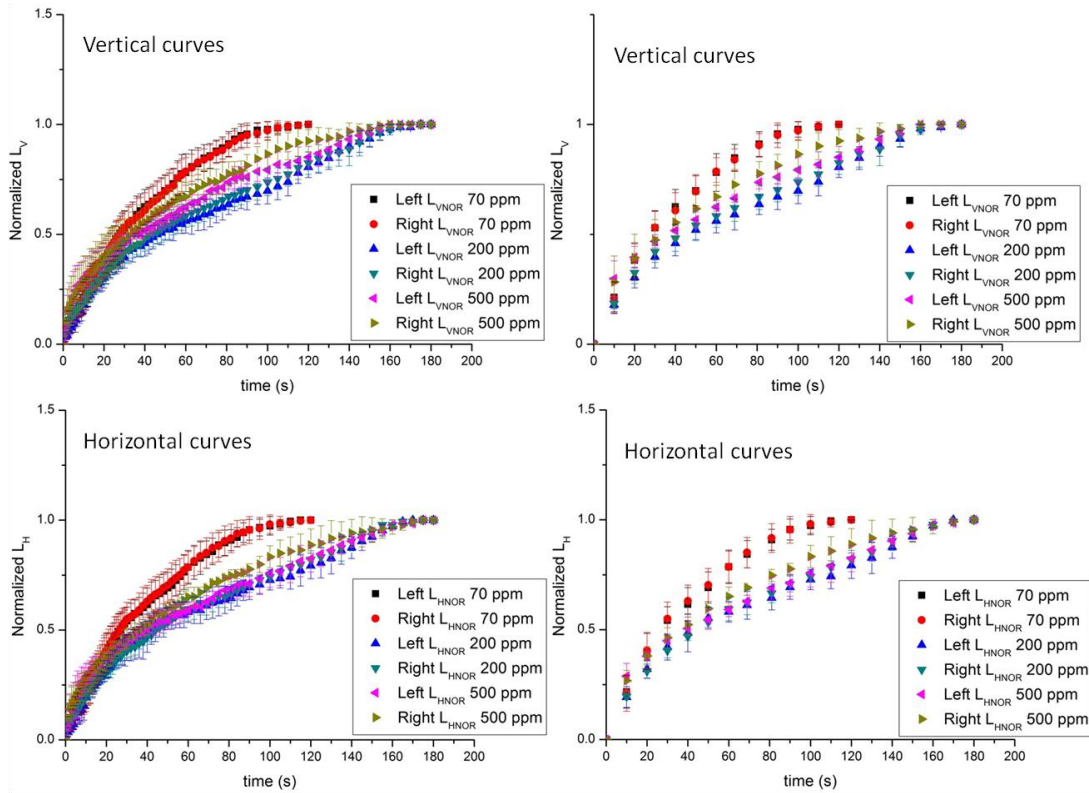

Figure 4.47 and Figure 4.48 show the average dimensional and normalized joint formations for 70 ppm, 200 ppm and 500 ppm in linear Cartesian coordinates, with a time interval of 1 second and 10 seconds (for the sake of clarity) at left and right, respectively.

**Figure 4. 47** Triple line kinetics under 70 ppm, 200 ppm and 500 ppm conditions

As mentioned in previous sections, the duration of evolution of the joint formation is around 100 seconds and 160 seconds for 70 ppm/200 ppm groups, and 500 ppm group, respectively. In addition, the joint fillet formation is highly symmetric under 70 ppm condition. With an increase in oxygen level in the chamber, the asymmetry

of the kinetics/joint topography increases. Under the 200 ppm condition, asymmetry is only noted in vertical dimension for a smaller evolution time duration (120 s ~ 160 s). Under the 500 ppm condition asymmetry is observed in both vertical and horizontal directions for a larger-time duration (between 40 s ~ 160 s).

**Figure 4.48** Normalized triple line kinetics under 70 ppm, 200 ppm and 500 ppm conditions

It is found that the joint formation is completed in a shorter time (that is, the triple line movement is faster) under 70 ppm condition than under 200 ppm and 500 ppm condition. Note that, the formation curves under 500 ppm condition are slightly above those under 200 ppm condition. That is, the rate of growth appears to be larger for 500 ppm but both are rather slow when compared with the more ideal conditions. This may be an artifact of experimentation because the data are primarily associated with the cross-section at the location of  $z=0$  mm along the joint fillet direction (where the focus is) and the geometric configuration at the edge has notable influence on joint formations under both 200 ppm and 500 ppm

conditions (See relative deviations for each group, Table 4.3, 4.6 and 4.9). But at different locations along the depth direction, the formation between 200 ppm and 500 ppm conditions are not the same as for the joint formation at 0 mm. Comparing the data in Table 4.6 with those in Table 4.9, it is discovered that data associated in Table 4.6 is larger than those in Table 4.9. Thus, overall, it is reasonable to speculate that actual kinetic curves of 200 ppm should be above those of 500 ppm at correspondent location along the depth direction. However, most likely, both 200 and 500 ppm cases belong to the same level of impact of the atmosphere on the kinetics (the impact most likely has to be measured on a logarithmic scale so that 500 and 200 ppm's are close to each other).

## CHAPTER 5: CONCLUSIONS AND FUTURE STUDY

The kinetics of wedge-Tee joint formation of aluminum brazing on a reactive substrate in a Controlled Atmosphere Brazing furnace under 5 different oxygen level conditions has been researched. Joint formation evolutions more or less conform to a theoretical Washburn type model for oxygen concentrations equal or smaller than 200 ppm. The non-uniformity of the joint formation under these conditions is negligible. Non-uniformity and asymmetry of the joint formation was well documented for larger oxygen concentration (500 ppm and 2000 ppm conditions). It is demonstrated that under dry air condition, the joining formation is unable to occur. It was realized that the oxidation of the clad has significant impact on the uniformity of joint formation. The joint formation micrographs were investigated, focusing on core erosion in the vertical piece and horizontal substrate.

### 5.1 Summaries and Conclusions

The following conclusions can be made from this thesis work:

(1) Joining process can be divided, in general, into 3 phases:

- a) Initial Phase: Lasts for about 20 s (70 ppm), 15 s (200 ppm) and 20 s (500 ppm);
- b) Power Law Phase:  $n=0.525$  lasts for about 80 s under 70 ppm condition ,  $n=0.525$  lasts for about 145 s under 200 ppm condition and  $n=0.463$  lasts for about 120 s under 500 ppm condition;
- c) Equilibrium Phase: Beyond 100 s (70 ppm) and beyond 160 s (200 ppm and 500 ppm).

(2) With an increase of the oxygen level, the fillet formation of joints deteriorates:

- a) The rate of joint formation evolution decreases;
- b) Non-uniform spreading appears with an increase in oxygen level concentration above 200 ppm;
- c) Non-

uniform joint formation fillet cross-section in axial direction of the joint formation is sizable if oxygen level concentration is larger than 500 ppm.

(3) 2-D Configuration (uniform fillet) of joint formation can be secured under 70 ppm and 200 ppm conditions; not valid at the 500 ppm and 2000 ppm levels.

(4) Joining cannot occur (no surface tension flow) under 200000 ppm (air) condition. Any produced liquid metal re-solidifies *in situ*.

(5) Local horizontal direction core dissolutions (on a vertical member of the wedge-tee joint) are more significant than vertical direction substrate dissolutions (on a horizontal member – brazing sheet).

(6) Geometric configuration of a sample may influence joint formation under a high oxygen level (200 ppm, 500 ppm and 2000 ppm) since the molten metal flow kinetics at the sample edge and along the depth direction differs.

(7) 2 hour of purging of specified composition of the Nitrogen background atmosphere is sufficient for the controlled atmosphere brazing in this study.

## **5.2 Future Study**

The following topics should be investigated in order to understand the mechanism of an aluminum alloy brazing on a substrate in a T-joint configuration.

(1) Increase the statistical confidence of the joint topology data set. A large number of tests have been executed but a limited number of joint cross sections after brazing have been analyzed. More samples from each group need to be processed to investigate the development of clad-core interface with the help of SEM and extend this impact to understand the consequences related to kinetics (i.e., how the interface reaction impacts the kinetics).

(2) A theoretical modeling of the triple line kinetics under 70 ppm of Oxygen condition can be performed based on the collected data (an acceptable reproducibility since the relative errors between measurements from OCA and those from polished samples are small and kinetics curves collapse to the same domain in multiple tests). The modeling has to identify the multi-phase character of the kinetics curves and follow the impact of inertial, surface tension and viscosity forces. The asymptotic termination of the joint formation vs. the removal of the available liquid phase has to be considered through the conservation of mass.

(3) Investigate the exact position of the threshold of oxygen level impact between 2000 ppm and 200000 ppm beyond which the joint formation will not occur.

## Appendix 1: Gas Sources specification data from the supplier

Gas type*	O <sub>2</sub> level in thesis (ppm)	Certified O <sub>2</sub> concentration (ppm)	Certified Moisture (ppm)	Notes

## Appendix 4: FEM verification of uniform temperature distribution on the test horizontal substrate during joint formation evolution

The geometric model and meshed model for the test sample configuration are presented below.

The temperature distribution on the substrate during the joining process between 850s and 1030s is shown in the following top view: (The probe represents the temperature of the substrate location where the thermocouple is positioned.)

The properties of materials used related to this analysis are assumed to be constant and are summarized in the following table.

Parts	Material	Density (kg/m <sup>3</sup> )	Thermal Conductivity (W/m·K)	Specific Heat (J/Kg·K)	Emissivity
Ceramic* Tube	96% Al <sub>2</sub> O <sub>3</sub>	3720	25	880	0.9
Copper Plate**	Copper	8933	401	385	0.78
Substrate**	AA3003 H24***	2730	171	880	0.2
Vertical Piece**	AA3003 H14***	2730	159	893	0.2

The average convective heat transfer coefficient of Nitrogen is 9.5 W/m<sup>2</sup>·°C. It is based on an assumption of forced convection over the flat plate using the convection heat transfer correlations<sup>52</sup> for external flow with Laminar flow and Pr > 0.6 conditions. The atmosphere temperature (450 °C) in the ceramic tube is taken as the average built-in thermocouple (Figure 2.1) temperature throughout the test time. Thermal radiation is the dominant heat transfer in this model and is based on Stefan-Boltzmann Law<sup>52</sup>.

Conduction part is based on heat diffusion equations. It is assumed in this analysis there is no radiation heat transfer exchange between surfaces composing the samples geometry inside the ceramic tubes (Only radiation exchange between ceramic tube inner surface and sample surfaces). ANSYS Thermal Solver used the following two equations to calculate the radiation heat transfer rate between two surfaces i and j and conduction in the respective components:

$$Q_i = \frac{1}{\left(\frac{1 - \varepsilon_i}{A_i \varepsilon_i} + \frac{1}{A_i F_{ij}} + \frac{1 - \varepsilon_j}{A_j \varepsilon_j}\right)} \sigma (T_i^4 - T_j^4)$$

$$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2} = \frac{\rho_i c_{pi}}{K_i} \frac{\partial T}{\partial t}$$

Where,

$Q_i$  = Radiation heat transfer rate between two surfaces, W,

$\epsilon_i, \epsilon_j$  = effective emissivity of surface i and j,

$F_{ji}$  = radiation view factors, defined as the fraction of total radiant energy that leaves surface i which arrives directly on surface j,

$A_i, A_j$  = area of surface i and j,  $m^2$ ,

$\sigma$  = Stefan-Boltzmann constant,

$T_i, T_j$  = absolute temperature of surface i and j, K,

$K_i$  = Conductivity of each material, W/m·K.

The calculation is performed by ANSYS Thermal solver. The element type used in the modeling is SOLID90 with total elements 3967. The following figure shows the temperature profiles of the experimental measured thermocouple temperature and numerically determined temperature at the location that is coincident to the external thermocouple position during the joint evolution time. There is no obvious temperature non-uniformity on the substrate and due to the geometric symmetry of the sample configuration the thermocouple was positioned only in the one side of the substrate.

It can be clearly seen that there is a little difference ( $<1^\circ\text{C}$ ) between maximum and minimum temperature on the substrate during joining process. Hence, it is verified that the temperature distribution is virtually uniform during the period of the joint formation evolution. The temperature reading from the external thermocouple can be assumed to be the temperature at the joint location.

**Appendix 5: External thermocouple temperature data for all tests**

## Appendix 6: Uncertainty determination of kinetics data

The uncertainty of measured triple line location for a certain test group at each recorded time specified in 3.3.1 is considered to be related to standard deviation based on the number of tests in each group conducted (Precision Index<sup>60</sup>). The uncertainty of measurement for a particular test within that test group is hard to define since the measurement (Figure 3.8 and Figure 3.10) uncertainties are heavily dependent on baseline selection in each test (Bias Error<sup>60</sup>).

Hence, the triple line location for a certain test group can be expressed as:

$$L_{V(H)} = L_{Avg} \pm U$$

Where,

$L_{V(H)}$  = Vertical or horizontal triple line location for a certain test group,

$L_{Avg}$  = Average triple line location from the measurements at each test performed in a particular test group:

$$L_{Avg} = \frac{\sum_1^n L_n}{n}$$

Where,

$L_n$  = measured vertical or horizontal triple line location for each test in the test group,

$n$  = Number of tests performed in the particular test group,

$U$  = Uncertainties of each test group:

$$U^{60} = \sqrt{\frac{\sum_1^n (L_n - L_{Avg})^2}{n}}$$

## VITA

### Name

Fangxiao Dong

### Place of Birth

Shanghai, China

### Education

B.E. in Thermal and Power Engineering (09/2003 – 07/2007), Shanghai University of Electric Power, Shanghai, China

### Experience

- Research and Teaching Assistant (08/2010 – 05/2013), Brazing Laboratory, Institute for Sustainable Manufacturing, Department of Mechanical Engineering, University of Kentucky

### Publications

H. Fu, F. Dong, D.P. Sekulic, S.Dj. Mesarovic, M. Krivilyov. "Surface Tension Driven Kinetics of the Triple Line of a Liquid Metal Free Surface", IMECE2013, November 13-21, San Diego, California, USA, 2013 (Submitted)
