## Acknowledgments

First it is only appropriate to acknowledge my principal investigator and mentor Dr. Gary W. Daughdrill. This work would not have been possible without his guidance or through the funding of his grants: from the American Cancer Society (RSG-07-289-01-GMC) and the National Science Foundation (MCB0939014). I would also like to thank my academic committee Drs Yu Chen, Stanley Stevens, and Sandy Westerheide for their help support and patience. Some of the work presented in this project was done with the help of other lab personnel like our undergraduate volunteer Nicolao Bakomihalis who was a tremendous help in preparing some of the PRE samples for analysis. Also a previous undergraduate and later lab technician to acknowledge is Katie Mishall who carried out the ITC experiments and aided in preparing the samples for SAXS analysis. The SAXS data acquisition and analysis was carried out by Dr. Veronique Receveur-Brechot ${ }^{1}$.

The cell studies carried out in Chapter 4 were conducted by our collaborators François Theillet ${ }^{2}$, Andrea Katzer ${ }^{3}$, Wanda Manieri ${ }^{4}$, Phillip Selenko ${ }^{2}$, and Alexander Loewer ${ }^{3}$. Finally a special thank you must be made to

[^0]Stepan Kashtanov and Dr. Marty Ytreberg Ph.D ${ }^{5}$ for their continuing development of the BEGR methodology and Stepan specifically for his help completing Chapter 5.

#### Abstract

Intrinsically disordered proteins (IDPs) are both common and integral to proper cellular functions. Intrinsic disorder is found in proteins across all phyla, with increased prominence in eukaryotic systems. IDPs are known to participate in vital cellular pathways, and their improper functioning results in numerous disease states, including cancers and neurodegenerative diseases. All proteins are dynamic in nature, occupying a range of conformational flexibilities. This inherent flexibility is required for their function, with ordered proteins and IDPs representing the least flexible, and most flexible, respectively. As such IDPs possess little to no stable tertiary or secondary structure, they instead form broad ensembles of heterogeneous structures, which fluctuate over multiple time scales. Although IDPs often lack stable secondary structure they can assume a more stable structure in the presence of their binding partners in a coupled folding binding reaction.

The phenomenon of the dynamic behavior of IDPs is believed to confer several functional advantages but remains poorly understood. To that end the dynamic and structural properties of a family of IDPs - p53 transactivation domains (TAD) was measured and compared with the sequence divergence. Interestingly we were able to find stronger correlations between the dynamic properties and the sequence divergence than between the structure and sequence, suggesting that the dynamic properties are the primary trait being

conserved by evolution. These correlations were strongest within clusters of the IDPs that correlated with known protein binding sites. Additionally, we show strong correlations between the several available disorder predictors and the backbone dynamics of this family of IDPs. This indicates the potential of predicting the dynamic behavior of proteins, which may be beneficial in future drug design.

The limited number of atomic models currently determined for IDPs hampers understanding of how their amino acid sequences dictate the structural ensembles they adopt. The current dearth of atomic models for IDPs makes it difficult to test the following hypotheses:

- The structural ensembles of IDPs are dictated by local interactions.
- The structural ensembles of IDPs will be similar above a certain sequence identity threshold.

Based on the premise that sequence determines structure, structural ensembles were determined and compared for a set of homologous IDPs. Utilizing orthologues allows for the identification of important structural features and behaviors by virtue of their conservation. A new methodology of creating ensembles was implemented that broadly samples conformational space. This allowed us to find recurring local structural features within the structural ensembles even between the more distantly related homologues that were processed. This method of ensemble creation is also the first method to show convergence of secondary structural characteristics between discrete ensembles.

## Chapter One - Introduction

## Intrinsically Disordered Proteins

## General characteristics of IDPs

All proteins are dynamic and require a certain degree of flexibility for their functioning. A large proportion of proteins are classified as ordered proteins, forming stable secondary, tertiary and often quaternary structures that are necessary for their functionality, and exhibiting a small pool of unique conformations that they may fluctuate between. A classic example would be the inability of oxygen to reach the heme group in hemoglobin without some dynamic behavior (1). Many proteins however, do not form stable secondary or tertiary structure, yet are still biologically active. These proteins, termed intrinsically disordered proteins (IDPs), are highly dynamic, and do not form a single structure. They instead form a broad ensemble of heterogeneous conformations that fluctuate over multiple timescales (2-10). A polypeptide's behavior, and therefore function is determined by its amino acid sequence. There are inherent differences in the amino acid composition of IDPs, including a higher proportion of residues with charged and polar side-chains a depletion in residues with hydrophobic and bulky aromatic side-chains. IDPs also tend toward lower sequence complexity than ordered proteins. These differences allow algorithms
to identify disordered regions that are 30 amino acids or longer with $75-80 \%$ accuracy (11-14).

The abundance of disordered proteins can be estimated using several sequence based disorder predictors. IDPs are widespread in nature, and are found to be enriched in signaling, regulation, and recognition functions. Eukaryotes exhibit a higher fraction of disorder than prokaryotes or archae. The greater prevalence in eukaryotes is believed to be a result of the increased cellular organization $(4,6,15-23)$. It is predicted that $55 \%$ of eukaryotic proteins contain at least one disordered region of 40 residues or longer (10).

## Structure and dynamics

Ordered proteins collapse to form a compact hydrophobic core, which helps to stabilize their secondary and tertiary structures. In contrast, IDPs possess a low fraction of nonpolar residues, precluding the formation of a hydrophobic core to stabilize any secondary and tertiary structure (4, 24-26). The resulting difference in conformational freedom can be illustrated by their different energy landscapes. The landscape of an ordered protein might be described as having relatively few "wells" and perhaps one well that is deeper than most- representing the most stable conformation, there would also likely be a large energy penalty between the most populated conformation and the lesser populated ones. IDPs in contrast would have a "flatter" landscape with relatively shallow wells, and small - if any- significant penalty between the available conformations, allowing the IDP to populate multiple conformations or fluctuate
between them. A representation of the resulting energy landscape for IDPs compared with ordered and partially ordered proteins is shown in Figure 1.

Figure 1 - Energy landscape model for proteins. Notice the shallowness of the local free-energy minima of the landscape for the IDPs in their native unbound vs. their bound states.

The lack of folding observed in IDPs could lead to the assumption that they exist in a random coil state, which may be defined as the state where the phi and psi dihedral angles populate a Boltzmann distribution that samples three dimensional conformational space freely, somewhat like a chemically unfolded protein (27). However, IDPs exhibit a degree of collapse that is inconsistent with this random coil model and also show a broader range of compactness with respect to polymer length when compared to chemically unfolded proteins(24, 28). In addition to a lack of hydrophobic residues, IDPs also show a higher net
charge than ordered proteins and a higher fraction of proline residues. The high net charge prevents collapse of the protein through intramolecular repulsion of like charges, while the high number of prolines tends to extend and stiffen the chain and can act to disrupt secondary structure formation and/or stabilization.

Because IDPs are not well represented by random coil models and have a high degree of variability in their structural landscapes, several groups have developed classification schemes to differentiate varying degrees of dynamic behavior. This is difficult because IDPs could be completely unstructured, have some transient secondary structure, possess long disordered loops, or exist in a configuration where multiple ordered domains are joined by flexible linkers. This variability makes it difficult even to define distinct boundaries between ordered, and disordered proteins, never mind cutoffs between variations in IDPs themselves (29). One plausible classification scheme differentiates them as follows: native coils, native pre-molten globules, and native molten globules, with native coils having the least structural rigidity and native molten globules having the most (10, 24, 25).

Structural analysis of IDPs is proving to be more challenging than compact ordered proteins. This is due to their flexible nature, which makes them difficult if not impossible to crystalize, often precluding X-ray crystallography. To date, only a relative few structural ensembles for IDPs have been determined. This is in part due to the lack of a general approach to generate and characterize the structural ensemble of an IDP, although several groups have used a variety of techniques (8, 30-37). However, since only a few ensembles have been
determined and because the ensembles are underdetermined, it remains unclear how accurately these ensembles are representing the true equilibrium ensemble (38). The studies that have been conducted reveal some notable features. Some IDPs are found to have regions of transient secondary structure often corresponding to known binding sites, there have also been some transient longrange contacts observed (13, 39-43). The transient structure displayed by these binding sites is often stabilized upon binding or post translational modification (PTM) (40, 44-52).

The dynamic behavior of IDPs is to be necessary for function as its loss can result in loss of the correct function $(53,54)$. Like the structural properties of IDPs, the dynamics are difficult to study as a single IDP can display dynamic behavior over multiple time scales, as it fluctuates between all the available conformations. Any NMR or X-Ray crystal analysis would represent the ensemble averages of these behaviors, therefore despite it's apparent importance in protein function the molecular dynamics of IDPs remains poorly understood $(53,55,56)$. The highly dynamic nature of is believed to confer a number of functional advantages in specific areas like higher specificity, increased binding kinetics, and accessible PTM sites (29).

## Functions

IDPs are functional, and are enriched in certain functions like signaling, regulation, and recognition. Earlier it was mentioned that some IDPs exhibit transient secondary structure that is stabilized upon binding. Some IDPs display
no apparent structural preferences but will still fold upon binding with their partners $(6,49)$. This coupling of folding to binding can help explain the central role IDPs play in so many cellular functions, ligand recognition and binding, harboring PTMs, as well as playing key roles in cellular signaling, and acting as hubs in protein networks. Other functionality that does not involve the IDP binding is for a disordered region to act as an entropic tether or flexible linker.

## Recognition/protein binding and PTMs.

IDPs exhibit binding promiscuity (57-59), where one IDP is able to specifically recognize and bind to multiple partners (6, 7, 27, 60). This binding promiscuity may be explained by the large interaction surface and the highly dynamic nature of IDPs. The increased surface area per residue is a result of the lack of stabilizing intramolecular interactions. If the residue is not interacting with another in the same polypeptide, and is not buried in a hydrophobic core then it is interacting with solvent and is more readily available to interact with other molecules. The flexibility also enables IDPs to specifically interact with multiple binding partners over a comparably short sequence, because the IDP is able to take on multiple conformations. The increased surface area and flexibility also allows IDPs to overcome steric hindrances in large complexes, as the IDP is able to wrap around its binding partner (9, 61, 62).

IDPs are enriched in PTM sites. In fact, disorder prediction protocols have even been included in phosphorylation prediction algorithms to improve their accuracy $(9,23,63,64)$. It is possible that the flexible nature of the IDPs allows
for easy the binding of the kinases, ubiquitinases and other protein modifiers (65). The flexibility and binding promiscuity as described above may also allow many modifiers to bind to and modify a comparatively short sequence. The PTM of a protein can lead to conformational changes in ordered sequences and can also initiate disorder to order transitions, and vice versa, thereby affecting their potential binding interactions and functionality (65, 66). Due to the flexible nature of IDPs, it is possible that a PTM can induce significant local structural reorganization of an IDP or IDR without the structural consequences of the PTM of an ordered protein (65).

## Signaling and network hubs.

Cellular functions are integrated by protein-protein interaction and signaling networks. While there is still debate about the type of network/s employed by biological systems, current evidence at least suggests the that the primary type utilized is a form of scale free network (SFN) (17). A SFN might be described as an interacting network consisting of nodes and hubs, where nodes possessing few interacting partners are interconnected by hubs possessing a multitude of interacting partners. The SFN model would confer an increased tolerance for random mutation, since most proteins would act as nodes and therefore most mutations would leave the integrity of the network intact, however mutations to any proteins acting as a hub would have a cascading effect through the network (67). A study of the protein interaction network of S. Cerevisiae seems to support this, finding that $93 \%$ of the proteins studied had less than six partners, of which approximately $21 \%$ were required for survival. This is in
comparison with only $0.7 \%$ of the proteins studied showing more than 15 partners, of which $62 \%$ were proven to be required for survival (68). The ability of IDPs to form complexes with high specificity to multiple binding partners explains their prevalence in signaling, recognition, and regulation, and makes them ideal for forming the hubs of a SFN model of protein signaling networks. Many of the putatively identified hubs are in fact IDPs, and many of the hubs that are not IDPs interact almost exclusively with IDPs $(17,69)$.

## Flexible linkers.

The separate domains of multi-domain proteins are often connected by linker regions. The Argos and George laboratory groups separately created databases to study these linker domains. Analysis of these databases revealed certain characteristics of these linker domains $(70,71)$. The majority of the shorter linkers had rigid defined structures, mostly alpha helical and hydrophobic in nature, while the longer linkers displayed more flexible and hydrophilic natures. The shorter rigid linkers essentially act to separate the individual domains, possibly preventing unwanted intramolecular interactions (72). The longer linkers were found to be far more flexible, showing mostly random coil characteristics. These flexible linkers encompass some of the most dynamic IDPs. Their function seems to be that of a simple tether between separate domains, defining the proximity of the folded domains (73-75). In contrast to the shorter rigid linkers, the flexible linkers may allow, or encourage weaker intramolecular interactions. They are however, enriched in prolines which may serve to increase their rigidity.

## Coupled folding and binding

The coupling of folding and binding is a frequently observed phenomenon in IDPs, and can involve an IDP to IDP, IDP to ordered protein, or IDP to nucleic acid interaction (7, 76-78). The putative purpose of coupled folding and binding is to balance high specificity with reasonable affinities. Binding specificity increases as compatible molecular interface between two molecules increases. This normally results in increasing affinity, which may become a problem as increasing affinity slows the kinetics down to a point of hampering the processivity of the interaction $(50,78,79)$. However, by coupling the folding to binding of an IDP, an entropic penalty is introduced, lowering the overall affinity while maintaining the necessary specificity of the interaction. This may also act to increase the specificity because only a "good" match for that binding interface would be able to overcome the included entropic penalty. While there are theoretical studies supporting this general hypothesis, it has yet to be vigorously tested experimentally (80). There are two main models that describe the coupled folding and binding reaction: conformational selection (CS), and induced fit (IF) (78, 81).

## Conformational selection and induced fit.

The CS model is based on the hypothesis that within the structural ensemble populated by the IDP, there will be conformations resembling the bound state that are selected by the binding partner - the IDP folds then binds $(52,78)$. There is evidence that this may be the mechanism employed by the cyclin-dependent kinase inhibitor 1B's (CDKN1B) interaction with Cyclin-
dependent kinase 2 (Cdk2), as NMR and molecular dynamics (MD) simulations find CDKN1B to exhibit a structure similar to its bound state (82).

Alternatively, the IF model proposes that a multitude of an IDP's conformations are fit for a weak association with the binding partner, then proceed to fold into the final bound state, using the partner as a scaffold - the IDP binds then folds (78). An example of induced fit is the binding of the disordered phosphorylated kinase inhibitor domain (pKID) to its targets via a weak encounter complex. The encounter complex remains largely disordered before forming a partially structured intermediate, and finally a fully bound state (83-85). The more extended state of the IDP in the IF model would also result in an increased capture radius. This behavior might be described by a "fly-casting" model, where a mostly unfolded IDP binds to its ligand weakly at a relatively large molecular distance or capture radius, followed by the more specific binding of the folded complex $(86,87)$. This increased capture radius of the binding may result in increased binding kinetics due to lower free-energy barriers associated with the initial binding $(29,86,87)$. Computationally the pKID/KIX system also provides support for fly-casting, as increasing the helical content of the solution state (the structure formed when bound) resulted in a decreased association rate, while increasing the transition states available increased the association rate without changing the binding mechanism $(87,88)$.

Figure 2 - Conformational Selection and Induced Fit. Illustration representing CS and IF- proposed mechanisms of coupled folding and binding.

Either mechanism or even a combination of them is plausible, with some IDPs like staphylococcal nuclease showing signs of folding both before and after binding (89). Figure 2 illustrates how this might work, it shows an IDP fluctuating between its conformations, within this ensemble resides a few conformations fit for binding - as described by the conformational selection model. However, a much higher proportion of the ensembles' population is not in a conformation resembling the bound state but may begin associating with the partner weakly before fully folding $(40,52,55,78,90)$. Which mechanism is ultimately used or any bias toward one may depend on the dynamic behavior of the IDP in question. For example, a protein interaction site displaying strong transient secondary structural propensities and restrained backbone dynamics may be
biased toward the CS model. However, an IDP showing little transient structural propensities or significantly higher backbone dynamics in the interaction site may be biased toward the IF model.

## Evolution of IDPs

Many IDPs evolve more rapidly than their ordered counterparts as IDPs are more amenable to amino acid substitutions, repeat expansions, and insertions/deletions (91-94). IDPs are more tolerant of amino acid substitutions because most are expected to be neutral or nearly neutral, having little effect on the protein's behavior. This is in part due to the lack of a hydrophobic core, and minimal long range intramolecular interactions, and so even non-conserved mutations have mostly local effects. However, the changes are still under selective pressure, evidenced by the fact that certain changes are more tolerated than others. This profile of acceptable changes in protein sequence is also different from the mutation rates per residue type seen in ordered proteins, for example the few hydrophobic residues that IDPs do possess are highly conserved possibly due to their importance in forming the binding interfaces with partners (95). Despite this more rapid evolution, several studies have shown that the functionality of IDPs if not their sequences are still maintained (96-98). A study of the conserved flexible linker domain in the 70 KDa subunit of replication protein A (RPA70), for example, found that the dynamic behavior was conserved despite the negligible sequence conservation observed (96).

One of the aforementioned functions of IDPs is their ability to host and display PTMs. $(9,64)$. The evolutionary characteristics of IDPs may affect the evolution of PTMs observed in IDPs compared with those observed in ordered proteins (55). Studies on the rate of evolution for phosphorylation sites found that phosphorylated Ser and Thr were no more conserved than nonphosphorylated ones in the short term, but are more conserved across speciation events even if they are still more rapidly changing in IDPs than in ordered regions. It has also been noted that phosphorylated sites may shift positions in the most distant comparisons (99-102). As more comparisons are made between homologous families of IDPs these constraints maybe be revealed, providing insight into the importance of their flexibility, and other functions like coupled folding and binding.

## Disease states

Considering that IDPs are enriched in signaling and regulatory functions it is unsurprising that they play a role in human disease. A recent study has shown that the disruption of IDP regulation may contribute to disease pathogenesis (103). There are also many diseases associated with both proteins containing disordered regions and proteins that are completely disordered. Two completely disordered proteins, tau, and $\alpha$-synuclein are associated with Alzheimers disease with $\alpha$-synuclein also being associated with Parkinson's disease (76, 104, 105). Transmissible spongiform encephalopathies are also caused by a protein containing an intrinsically disordered region (IDR), the major prion protein $\operatorname{PrP}$ (106). A recent study showed that mutations in IDRs of a mixed
ordered/disordered protein can also result in disease, this - not surprisingly - can be due to loss of PTM sites, but more interestingly may also be caused by disorder-to-order conversions. This study found several mutations associated with human diseases are predicted to cause disorder to order conversions in p53 (tumor suppressor p53), BRCA1 (Breast cancer type 1 susceptibility protein), MECP2 (Methyl-CpG-binding protein 2), VHL (von Hippel-Lindau Tumor suppressor), TNNI3 (Troponin I, cardiac muscle), and SOD1 (superoxide dismutase) (53).

## Tumor Suppressor Protein p53

## General characteristics of p53.

The tumor suppressor protein p 53 ( p 53 ) is a transcription factor that plays a vital role in maintaining the genomic integrity of the cell, earning titles like "Guardian of the Genome," and the "Cellular Gatekeeper" (107, 108). These titles are well deserved, as p53 functions as a hub protein in a network responsible for deciding a cell's fate upon the detection of certain cellular stresses. The possible outcomes include halting cellular growth and proliferation in order to attempt to address the problems, entering senescence, or undergoing apoptosis. With these functions, it is not surprising that lack of $p 53$, or one of its upstream activators, can result in a genetic condition called Li-Fraumeni syndrome, which predisposes an individual to many forms of cancer, often at an early age and often several times throughout the affected individual's lifespan. The p53 gene is mutated in $30 \%$ to $50 \%$ of commonly occurring human cancers,
making it the most frequently mutated gene found in human tumors (see Figure 33) (109).

Figure 3 - Prevalence of mutation in the p53 gene of human tumors. Adapted from the p53 AIRC database as updated Nov 2010 (109).

## Structure.

Full length p53 is a 44 KDa protein that functions as a homotetrameric transcription factor. It consists of a N -terminal acidic transactivating domain (TAD) which is disordered, a polyprolyl domain PRD, a core DNA binding domain (DBD) an oligomerization domain, and a disordered C-terminal regulatory domain (REG) (See Figure 4) (110). It has several identified isoforms including N terminal and C-terminal truncations, that are the result of exon skipping (111). The N-terminal isoforms may function to suppress the transactivation potential of the full length isoform, as it is still competent to form tetramers and bind the DNA
but is lacking the TAD. The C-terminal truncations are assumed to also play a role in regulatory mechanisms $(111,112)$.

Figure 4 - Human p53 domain structure. Bottom shows the domain structure of p53 overlaid with IUPred disorder prediction plot (top). Values above 0.5 are predicted to be disordered (113).

## Regulation.

The activity of p 53 is tightly regulated; it is constitutively expressed at a high rate, though under normal cellular conditions it is maintained at low cellular concentrations with a short half-life, through degradation by the proteasome. This is an energetically expensive method of maintaining low cellular concentrations. However it allows for rapid regulation of protein levels. By simply blocking this degradation, a much more rapid increase in available protein levels is possible than by starting at transcription. The negative regulation of p53 is primarily carried out by the E 3 ubiquitin ligase murine double minute (Mdm2), the human orthologue of which is Hdm2, and its homologue MdmX (also called Mdm4). Mdm2 is an E3 ubiquitin ligase. Mdm2 binding to p53 immediately precludes the transcription activity of p53, leads to nuclear export, and also
ubiquitinates the carboxyl terminus of p53 targeting it for degradation by the proteasome (114). MdmX also binds to p53 preventing its transcriptional activities by limiting access to transcriptional co-activators, but has weaker ubiquitin ligase activity than Mdm2 (115). Conversely, positive regulators include ARF, which is able to bind Mdm2 and sequester it in the nucleolus, preventing its association with p53 (116). There also appears to be some interplay between the two Mdm homologues since they are able to form heterodimers. Interestingly, overexpression of MdmX abrogated Mdm2-mediated p53 degradation (117, 118). Loss of either homologue results in early embryonic lethality due to overactive p53 (114). It should also be noted that both Mdm2 and MdmX along with other negative regulators of p 53 , are upregulated by p 53 thus creating a negative feedback loop (119-121).

## Function of p53

## Classical pathway.

The classical model of p53 activation (Figure 5) posits that cellular stresses such as DNA damage; activate signaling pathways that lead to the phosphorylation of p53 at $\mathrm{S} 15, \mathrm{~S} 20$, and T18 within the TAD alters the structure of the amphipathic helix which Mdm2 and MdmX interact with, abrogating the binding event. The signals that can lead to p53 activation include X-ray and UV radiation, DNA damaging chemotherapeutic drugs, microtubule disruption, hypoxia, a deficiency of nucleotide precursors, nitrous oxide, low pH and, prevention of RNA or DNA synthesis (114). The network of PTMs that
activate/modulate p53 activity is extensive, as can be seen in Figure 6. Since different kinases are triggered by different cellular stresses, it allows for a p53 response "code" where the specific responses of p53 might be biased according to which residues have been modified, and the type of the modification. Some of the more studied PTMs are within the p53-Mdm2/MdmX interaction site. S15 phosphorylation by ATM and ATR, or T18 and S20 by Chk2 are generally associated with loss of Mdm2 binding and therefore p53 accumulation and activation (122-124). Many of the other PTM sites have been implicated in biasing which genes are transactivated, thus biasing the final outcome of the stress response (125-130). There are many more PTM sites in each p53 molecule, allowing for a complex "code". As mentioned earlier, IDPs are well suited for multiple binding partners facilitating the binding of modification enzymes (131).

Much of the functionality attributed to the PTMs regulation of p53 is derived from studies conducted in vitro, however more recent studies conducted using in vivo mouse models did not have the expected phenotypes. The phenotypes do confirm some importance of the PTMs but they seem to indicate that regulation of p53 is more strongly affected by the modulation of Mdm2 and MdmX concentrations. MdmX levels seem to have a greater impact on growth arrest in comparison with apoptosis. Also it has been demonstrated that the auto-degradation of Mdm2, and the Mdm2 mediated degradation of MdmX plays an important role in the p53 mediated DNA damage response (132, 133). The complete schematic of p53 regulation is extremely complex, and has yet to be full
understood, but it appears that the main regulatory mechanism might be the interplay between Mdm2-p53, MdmX-p53, and Mdm2-MdmX, with the PTMs playing a role in fine tuning p53s final output(134, 135).
a Unstressed Cell

b Cellular Stress activates Kinases

Figure 5 - Classical model of p53 regulation. a) In an unstressed cell Mdm2 binds to the TAD of p53 and ubiquitinates the C-terminus leading to degradation. b) Cellular stress triggers kinases to phosphorylate the N -terminus, disrupting Mdm2 binding leading to p53 accumulation, allowing its transactivation activities and possible cytoplasmic roles. Figure adapted from Toledo et al. $(114,136)$.

Figure 6 - Human p53 has many binding partners and PTM sites. Adapted from Meek et al. (110).

## Intrinsic apoptosis pathway.

In its role as a tumor suppressor, one of the main mechanisms p53 has at its disposal is the ability to induce apoptosis. p53-dependent apoptosis is primarily dependent on the transactivation activities of p 53 . With the correct "code" of PTMs and balance of Mdm2-MdmX, p53 will upregulate the expression of a number of genes that can initiate apoptosis, primarily through the intrinsic pathway (Figure 7) via the mitochondria. p53 also has a link to the extrinsic pathway through the upregulation of the Fas receptor, serving to sensitize the cell to external kill signals (137). p53 transcriptional targets include pro-apoptotic BCL2-like proteins, including BAX, and the BH3-only proteins PUMA and Noxa
(138, 139). PUMA and Noxa function by binding to anti-apoptotic Bcl-2 like proteins such as BCL2, and BCLX $X_{L}$, resulting in the release of cytochrome-c which binds Apaf1 forming the apoptosome, thereby activating the caspase pathway leading to apoptosis (139). There is some experimental evidence implicating p53 in a more direct role in apoptosis. These studies find p53 in direct interaction with several Bcl2-like proteins, acting to encourage oligomerization of pro-apoptotic $\mathrm{Bcl} 2-$ like BAK , and BAX and/or sequester the anti-apoptotic Mcl1, and Bcl-2, Bcl- $X_{\mathrm{L}}$ proteins (140-142). The direct interaction of p53 with the Bcl 2 -like proteins pathway is more controversial, with none of the mouse models being able to induce apoptosis without being able to transactivate pro-apoptotic genes (114).

Figure 7 - The intrinsic apoptosis pathway of p53 adapted from Ashkenazi (143).

## Binding partners.

As can be seen in Figure 6, p53 has many binding partners. Some of the most studied partners and the most relevant for this study are Mdm2, its homologue MdmX, and RPA70. Mdm2 functions as a 110KDa dimer, with its primary function is as an E3 ubitquitin ligase, and consists of an N-terminal SWIB/Mdm2 domain that binds p53's TAD, a C-Terminal RING finger domain, and a central acidic domain, all of which are essential for ubiquitination (144, 145). MdmX also functions as a dimer of similar size, and has a similar domain structure as Mdm2 but much weaker E3 ubiquitin ligase activity. As already described above, Mdm2 and MdmX play important roles in the regulation of p53 functionality. It is interesting to note, however, that Mdm2 is able to bind p53's paralogues p 63 , and p 73 , but does not seem to cause their degradation and may even activate them (111).

RPA is a heterotrimeric protein that binds to single stranded DNA (ssDNA), and functions in part to prevent the ssDNA from folding back on itself and forming secondary structures. It is essential for DNA replication, repair, and recombination. The three subunits comprising it are the $70 \mathrm{KDa}, 32 \mathrm{KDa}$, and 14 KDa subunits, with the RPA70 subunit being responsible for the high affinity it has for ssDNA (146). The TAD of p53 is capable of competing with ssDNA for binding to the 70 Kda subunit by molecular mimicry. This interaction has been hypothesized to be part of the maintenance of a small but immediately available source of p53 upon DNA damage (77, 147, 148).

## Evolution of p53.

## Conservation.

p53 is well-conserved through evolution, but like many IDRs, the TAD is not as strongly conserved as the ordered DBD, making it a useful model to study the differential evolution of both ordered and disordered proteins. As mentioned earlier, ordered proteins with as low as $30 \%$ sequence identities often have nearly identical folds and functions (149-153). Yet in Figure 8, an alignment of homologous p53TADs of 6 mammals shows a relatively broad range of similarities, with identities as low as $44 \%$ between dog and mouse over their full TAD sequences, to local identities as high as $92 \%$ between human and cow. These sequences processed by IUPred (a disorder predictor) show a wide range of predicted disorder probabilities for the homologues (see Figure 9). Figure 9 illustrates that despite the TAD's lower sequence identity compared with the ordered DBD, the pattern of predicted disorder at least appears to be conserved.

## Homologues.

There are three members of the p 53 family: $\mathrm{p} 53, \mathrm{p} 63$ and p 73 . Evolutionary studies seem to position p63 as the progenitor of the family, with p53 being the most recent addition.(154) Figure 10 shows the domain structural alignment and approximate \% identities for the homologues. All three genes code for an acidic amino terminal domain, DNA binding domain, oligomerization domain and a regulatory domain, p63 and p73, however also, include a carboxy

terminal sterile alpha-motif (SAM) domain not found in p53. They all act as transcription factors and have overlapping gene targets (154). Interestingly despite the similarity in the tetramerization domains, neither p63 nor p73 are
competent to oligomerize with p53, they do however form oligomers between each other (155). Such strong similarities would seem to indicate that the family would ultimately share redundant functions. And indeed both p63, and p73 are able to regulate the cell cycle and induce apoptosis. The p53 family members do not, however, share truly redundant functions (111). While p73 can play a role in apoptosis, it seems to lack the potency of p 53 , as p 73 is seldom found to be mutated in tumors (156). The p73 null mice do however suffer from neuronal developmental defects (157). p63, like p73, has a weaker association with tumorigenicity is required for proper epithelial development (158). Interestingly, certain isoforms of the family may be antagonizers of one another's functionality. The isoforms of lacking the N-terminal TAD are still able to bind to the gene targets and thus competitively inhibit the full length protein's transactivation functions (159). Recent studies are also elucidating a role for the p63 and p73 in germ line maintenance, with the ancestral gene preventing DNA damage in worms and flies (160).

## Tumor suppressor p53 as an IDP model.

p53 is a useful model system for studying disordered proteins. p53 is predicted to be disordered across approximately $50 \%$ of its length in its monomeric state. These regions of disorder are located in the transactivation domain (TAD), the tetramerization domain (TET) and the regulatory domain (REG). Only the DNA binding domain is found to be ordered in its monomeric state. The TAD of p53 (p53TAD) has been experimentally confirmed to be disordered and has transient helical characteristics. There are many ligand binding sites in the p53TAD, but the Mdm2 site exhibits the strongest propensities for secondary structure and forms a stable alpha helix when bound by its ligands $\operatorname{Mdm} 2 / \mathrm{MdmX}(36,46,161,162)$. Another binding site of interest is the RPA70 site, which shows only minimal transient structure in human p53TAD, but also folds upon binding. Transient long range contacts have been observed in this intrinsically disordered region (IDR) as well, facilitating the study of both phenomena $(36,43)$. Many of the PTM sites of p53 are located in the TAD, and these PTMs modulate the TADs binding events.

Studying p53TAD for its disordered properties will improve our understanding of the evolution of these IDR. This is because the p53TAD gives us the opportunity to study a family of disordered regions which should have conserved function based on the full length p53 sequence identities. The range of sequence identities over the full length and locally (See Figure 8) should allow us to make observations over a wide range of sequence conservation. We can also use the p53TAD system to study coupled folding and binding, because there
are two binding sites with different levels of sequence identity and structural and dynamic behavior, but that both show coupling of folding to binding. Specifically understanding the behavior of this IDR will aid in the understanding of the p53 network because this region's behavior plays a major role in the regulation of p53 and its decisions in cell cycle regulation.

# Chapter Two - NMR Measurements of Structure and Dynamics of p53TAD Homologues 

## Rationale

Fully identifying the distribution of structures that make up the population weighted average of chemical shifts is a significant challenge in structural biology. NMR is an excellent tool for the study of IDPs, as it elucidates both structural and dynamic characteristics at the single amino acid resolution (27, 163-165). NMR was used to measure the local structural propensities via chemical shifts ( $\delta$ ) and residual dipolar couplings (RDCs), and intramolecular distances via paramagnetic relaxation enhancement (PRE). NMR was also used to measure the dynamic behavior of this IDP family by measuring the NHNOEs. The structural data can then be used to generate structural ensembles, while both the structural and dynamic properties are compared to the sequences in an evolutionary context. This chapter outlines and explains the NMR techniques used while later chapters focus on interpreting the resulting data.

## Protein purification scheme

All proteins were purified using affinity chromatography, tags were cleaved using the appropriate protease, and then the proteins were cleaned up using size exclusion columns. Specific details on the purification process can be found in

Chapter 7. Protein concentration was calculated using each protein's calculated extinction coefficient as determined by the program protparam (available at expasy.org) and the measured absorbance at 280 nm using a nanodrop ND1000 from Thermo Fisher. Sample concentrations were kept as close to 0.3 mM as practical. All the p53TAD constructs proved to be highly soluble, showing no precipitation issues in this concentration range.

## Nuclear Magnetic Resonance Spectroscopy

All presented results were conducted using a Varian VNMRS 600 MHz spectrometer equipped with a triple resonance pulse field Z-axis gradient cold probe.

## Assignments

The HSQC is a high resolution two dimensional NMR experiment, the data collected from various HSQC spectra can be used for several analysis, like NHNOE, PRE, RDC, T1 and T2 relaxation (166-168). The HNCACB and HNCO are three dimensional NMR experiments that can be used to identify which resonances correlate with which residues (169-173). The HNCACB and HNCO require the protein to have both magnetically labeled N , and C , the experiments are designed such that the spin is transferred from the amide proton through the covalent bonds to the N and C atoms and back, yielding a signal that has resonances in the corresponding frequencies. This allows a spectra to be generated in three dimensions as seen in Figure 11, with the ${ }^{1} \mathrm{H},{ }^{15} \mathrm{~N}$, and ${ }^{13} \mathrm{C}$ making up the $x, z$, and $y$ axis respectively. For the HNCACB there is also a
weaker resonance coming from the previous residues' $C$ atoms. In the example provided the spin systems from residue 23 through 25 can be seen with the corresponding i-1 resonance allowing the resonances to be more accurately identified, the more resonances that can be backtracked to previous spin systems the greater the degree of confidence one can have in the assignments made as there is increasingly fewer possibilities of finding that sequence of amino acids or resonances repeating. This method has been used to make the resonance assignments of the p53TAD homologues shown in Figure 8

Figure 11 - Resonance assignments. Strips from the HNCACB spectra of Guinea pig. The ${ }^{1} \mathrm{H}$ dimension lies along the X -axis, the ${ }^{13} \mathrm{C}$ along the Y , and the ${ }^{15} \mathrm{~N}$ goes into the plane.

## Chemical shifts

A chemical shift is the resonance frequency of a given nucleus in relation to some standard within a magnetic field. Nuclei with a non-integral magnetic spin will partially align their spin states with a strong magnetic field yielding different energy levels. Some of the low energy nuclei can then be excited with a radio pulse and when allowed to relax back to the lower energy state energy, in the form of radio waves, is released. Similar nuclei will have a slightly different resonant frequency based on the amount of shielding afforded by the local electron environment. Thus the chemical shifts of a nucleus provide information about local atomic structure. In particular, the chemical shifts for the backbone atoms in polypeptides are sensitive to the dihedral angles phi and psi. Knowing these dihedral angles gives a good indication of the backbone structure for a polypeptide due to the partial double bond established by the pi electrons which results in the peptide bond being nearly planar between the $\mathrm{C}_{\alpha}$ atoms (Figure 12). These dihedral angles can be reliably estimated from the backbone chemical shifts of ordered proteins because significant fluctuations in the local conformational preferences are not expected for ordered proteins. Using chemical shifts to estimate the backbone dihedral angles for IDPs is more challenging because the chemical shift represents a population weighted average of the local conformational preference. Also IDPs possess little to no tertiary or secondary structure they do experience large-scale conformational fluctuations over multiple timescales further complicating the estimations of the
dihedral angles (2-10). The Chemical shifts for the backbone atoms can be found in Appendix A.

Figure 12 - Peptide bond. Shows the planar nature of the peptide bond, which is why the dihedral angles phi, and psi can be used to describe the backbone structure.

## Secondary chemical shifts. ${ }^{1}$

Secondary chemical shifts, $\Delta \delta$ are a convenient and accurate way to determine the secondary structure of a polypeptide (175-178). $\Delta \delta$ are a measure of how far a specific residue's chemical shifts, have deviated from a random coil. So the secondary chemical shift of the alpha carbon for a specific residue would be equal to its measured chemical shift minus chemical shift of the random coil reference for that amino acid. Structured proteins frequently show $\Delta \delta$ as high as +3.1 ppm for the alpha carbon indicating a stable alpha helix, (negative shifts are an indication of beta or elongated conformations). The $\Delta \delta$ for IDPs are generally

[^2]smaller due to their ability to sample three-dimensional space more freely and the $\Delta \delta$ reflect the weighted average of a diverse population. These small deviations are indications of a residue's bias toward secondary structure, be it helical or extended(179). Although these shifts are smaller, they are still useful in calculating some proportion of the population contributing toward a trend for some secondary structure (27). For example, if a residue has an alpha carbon shift of +1 ppm it could indicate $1 / 3.1$ or $\sim 32 \%$ trend toward helical structure, it should be noted that it is the trends that should be focused on not individual residues propensities.

The ensemble-averaged $\Delta \delta$ values for IDPs can be below or very near the digital resolution of the experiment. It is therefore paramount that the random coil values be as accurate as possible. One method of increasing the applicability of a reference library is to account for any inherent effects that neighboring residues might possess. These sequence corrections are often small, and would have little impact on the $\Delta \delta$ values of a structured protein, except perhaps those of proline, but these small corrections can have a large impact on the $\Delta \delta$ values of an IDP.

## Random coil libraries.

To estimate transient secondary structure for IDPs three random coil chemical shift libraries developed by Mulder, Wishart, and Schwarzinger were considered and it was decided that the reference created by Mulder was
the most reliable with the exception of glycines preceding prolines, so for these values the Schwarzinger values are used (179-181).

The three random coil chemical shift libraries described below were compiled using different strategies (179-181). The Wishart library was determined using a set of 40 protected linear hexapeptides with the general sequences of Gly-Gly-X-Ala-Gly-Gly, or Gly-Gly-X-Pro-Gly-Gly, where X refers to each of the 20 common amino acids. The measurements were made in the presence of 1M urea in an effort to eliminate any possible structural propensities of the short peptides. Gly was chosen to be the flanking residues due to its inherent flexibility. Alanine was placed in the $i+1$ position for its low steric hindrance and its inherent similarity to most of the amino acids. They also measured the values of each of the common amino acids with Proline in the $i+1$ position because it has a large, systematic effect on the chemical shift residue $X$. This is the only other near neighbor effect accounted for in the Wishart library (180).

The Schwarzinger library was developed accounting for the near neighbor effects of each of the 20 common amino acids within two of residue $i$. To accomplish this they created 20 protected linear pentapeptides with the sequence Gly-Gly-X-Gly-Gly, where $X$ once again represents each of the 20 common amino acids in turn. They measured the chemical shifts in 8 M urea at a pH of 2.3 to ensure that the peptides would be as close to their random coil shifts as possible. In addition to analyzing the chemical shift of amino acid X , Schwarzinger et al determined the effects residue X had on the chemical shifts of
each of the glycines, which permitted the generation of local sequence corrected random coil shifts (181). When using this library, care needs to be taken when considering the residues with acidic side chains because at pH 2.3 these residues are protonated, which could influence their random coil chemical shifts.

The most recent random coil chemical shift library was developed by Mulder and is called the neighbor corrected Intrinsically Disordered Protein database (ncIDP) (182). This database was generated using Single Value Decomposition (SVD) to analyze the chemical shifts and the nearest neighbor effects of 14 confirmed IDPs. This analysis comprised 6903 measured chemical shifts and results in lower root-mean-square-deviations from experimentally determined values than previous libraries, possibly due to conformational propensities of Alanine in the Wishart set, and due to the low pH and high urea used in the Schwarzinger set (179). However, due to the nature of IDPs there is a low sample size for residues that occur infrequently in IDPs (i.e. Tryptophan).

For the $\Delta \delta$ analysis, the ${ }^{15} \mathrm{~N}$ HSQC, ${ }^{15} \mathrm{~N}{ }^{13} \mathrm{C}$ HNCACB, and the ${ }^{15} \mathrm{~N}{ }^{13} \mathrm{C}$ HNCO, spectra have been collected for human, rabbit, guinea pig, mouse, cow, and dog p53TAD. Analysis of this data has resulted in the assignment of over $95 \%$ of the possible resonances for alpha carbons, beta carbons, amide nitrogens, amide protons, and carbonyl carbons to be made. Some resonance assignments are impossible due to the lack of an amide proton in proline residues, which prevents the assignment of the nitrogen of the proline, and any preceding residues carbonyl carbon. The alpha carbon $\Delta \delta$ from the orthologues can be seen in Figure 13. Alpha carbon shifts are the most sensitive to phi and
psi dihedral angles but a similar pattern of increased helicity in the Mdm2/MdmX binding region, and to a smaller degree in the RPA70 binding site can be seen in the carbonyl carbons' $\Delta \delta$ as well (Appendix A).

The near identical pattern of $\Delta \delta$ seen in the human, guinea pig, and rabbit Mdm2/MdmX binding region demonstrates that the secondary structure for this region is conserved. This is not surprising given the $100 \%$ sequence identity for the homologues in this region. The reduction in transient helical structure for mouse can also be explained based on the sequence. The change of a negatively charged residue at position 21 to a glycine is expected to increase flexibility and reduce helical propensity and this is indeed what is observed (see Figure 13). There is also a surprisingly strong region of helicity observed in the guinea pig homologue. This region aligns with the RPA70 binding site in human p53TAD. The observed variation in helical secondary structure for the p53TAD orthologues will provide an internal standard to assess how well the ensemble generation is working.

## Residual Dipolar Couplings

## Dipolar couplings.

Dipolar couplings are the interactions between two magnetic dipoles, they contain a great deal of structural information, however due to the rotational diffusion in an isotropic solution they average to zero or near zero. RDCs are derived from the dipolar couplings from molecules in an anisotropic solution; this will happen if the molecules are in partial alignment.

Figure 13- $\Delta \delta$ for the $\mathrm{C}_{\mathrm{a}}$ of the orthologues. Shaded boxes show the binding sites for Mdm2 and RPA70 and the asterisks show the positions of gaps in the sequence alignment.

## Partial alignment and residual dipolar couplings.

RDCs, like $\Delta \delta$ provide information on the bond vectors in pairs of amino acids, and have been used to demonstrate long range structure in ordered proteins (183, 184). While interpreting the results for IDPs remains more difficult, RDCs still provide information about the local sampling of phi, and psi space, and possible long-range contacts (32, 185, 186). IPAP-HSQC experiments were used to gather information about the local phi, and psi space, and perhaps some long range contacts (187). Figure 14 provides an example of human p53TAD RDCs showing the splitting in the N15 dimension using 3\% by weight anionic liquid crystals as outlined by Otting (186). The isotropic and anisotropic peak splitting is shown for selected residues, the isotropic splitting is near 94 Hz for every residue due to averaging, but negative couplings can be observed in the anisotropic splitting.

The partial alignment of macromolecules is achieved by creating of a lamellar phase using liquid crystals as described by Ruckert and Otting or by other methods including stretched acrylamide as described by Chou and Bax $(186,188)$. While RDCs provide information about the local phi/psi space and possible long range contacts, it is difficult to use them for de novo structural determination. However, calculating RDCs from a given structure is simple, making them an excellent tool to test the validity of a structure or ensemble of structures (189, 190).

Figure 14 - RDC Splitting of human p53TAD. Demonstrating the differential splitting of residues 9,18 , and 37 in the ${ }^{15} \mathrm{~N}$ dimension, the spectra was measured without ${ }^{1} \mathrm{H}$ decoupling in the ${ }^{15} \mathrm{~N}$ dimension.

The RDC plots of the human, guinea pig, rabbit and dog homologues can be seen in Figure 15 (values can be found in Appendix D). Measurements were attempted on the mouse homologue as well, but despite varying the temperature, the crystalline media and the pH there was too many peaks absent from the spectra, especially in the binding site. This may be due to either the peaks undergoing intermediate exchange between conformations, or perhaps an interaction with the liquid crystalline media. As with the $\Delta \delta$ data the strongest structural propensities are observed in the binding sites, particularly in the Mdm2 site. Human, guinea pig, and rabbit also seem to reach approximately the same
maximum RDC values $\sim-33$ again reflecting their identical sequences in that region, in comparison with the dog homologues' weaker structural propensities in that region.

Figure 15 - RDCs of the p53 homologues. RDCs of the four homologues where the measurements were possible.

## Heteronuclear nuclear Overhauser effect

NHNOE experiments measure the heteronuclear Nuclear Overhauser effect between the amide protons. This provides an unambiguous measure of protein backbone motion at single residue resolution. The ratio of peak intensity in the presence of and absence of the NHNOE relaxation period is proportional to the local correlation time for rotational motion for that peak. Local rotational correlation times for IDPs are typically shorter than those observed for ordered proteins with a similar molecular weight and can range from 100 ps to 1 ns , whereas structured proteins have correlation times around 10ns or slower. The values in between this reflect a relatively narrow range of rotational flexibility, with small positive values indicating restricted flexibility. Due to their lack of stabilizing secondary or tertiary structure IDPs have more variation in their local correlation times. This variation reflects the formation of transient secondary structure and, in some cases, transient long-range contacts (191). NHNOE relaxation is more sensitive than either transverse (t2) or longitudinal (t1) relaxation measurements in this particular range of correlation times.
${ }^{15} \mathrm{~N}$ labeled proteins are expressed, purified, and prepared as described previously, then ${ }^{1} \mathrm{H}-{ }^{15} \mathrm{~N}$ steady-state NOE experiments are recorded in the presence and absence of a $120^{\circ}$ off-resonance ${ }^{1} \mathrm{H}$ saturation pulse every 5 ms for a total of 3 s . A total of $512(\mathrm{t} 2) \times 128(\mathrm{t} 1)$ complex points were recorded with 128 scans per increment. The NHNOE values were determined by taking the quotient of the intensity for resolved resonances in the presence and absence of
proton saturation. Three measurements were made on each protein and the values were averaged.

Figure 16 - Relaxation rates. Notice the sensitivity of NOE ( ${ }^{1} \mathrm{H}-{ }^{15} \mathrm{~N}$ NOE) between the 10 and $8-\log \left(\mathrm{T}_{\mathrm{m}}\right)$, figure adapted from Kay.

The NHNOE results can be seen in Figure 17, the average intensity ratios and standard deviations can be seen in Appendix B. Negative NHNOE/NONOE values reflect shorter correlation times corresponding to a very flexible backbone. Positive NHNOE/NONOE values of 0.8 indicate the longer correlation times associated with structured proteins. Values closer to zero and slightly positive reflect increasing order i.e. transient secondary structure. In Figure 17 obvious trends can be seen, there is an increase in correlation times and thus decreased backbone flexibility in all orthologues corresponding to the Mdm2 binding site. Dog, mouse, and cow show the highest flexibility while human, guinea pig, and rabbit show the most restrained flexibility. Guinea pig and rabbit also show the
longest correlation times in the RPA70 binding region, though the guinea pigs correlation times do not seem to indicate transient structure as strongly as the $\Delta \delta$, did in Figure 13.

Figure 17 - NHNOE quotients for the orthologues. Negative intensity quotients are an indication of increasingly short correlation times and therefore increased backbone flexibility. Regions of positive ratios are indications of longer correlation times and therefore less backbone flexibility and possibly transient secondary structure

## Paramagnetic relaxation enhancement

Paramagnetic relaxation enhancement (PRE) may be used to estimate internuclear distance averages for the structural ensembles of IDPs with a range of up to $30 \AA$, allowing for structural studies of IDPs ensembles (34, 192, 193). PRE is the result of the interaction of an unpaired electron's nuclear magnetic dipole with another NMR active nucleus in the protein, in this case the amide proton. This interaction increases the relaxation rate of the proton as a function of the distance between dipoles, resulting in peak broadening, and reduction in peak intensity as a function of each proton's distance from the unpaired electron (194). A spin label baring an unpaired electron can be covalently attached to a specific site on a protein, allowing distance measurements to be made based on the peak intensity reduction of the protons (195). These distance restraints may then be used to aid in protein structure modeling (196-198). PRE experiments are one of the few methods able to make any long range structural measurements of IDPs, and has been used to identify transient long-range contacts in p53, synuclein, and several other IDPs $(34,43,192)$.

The paramagnetic spin label used in this study is MTSL (Figure 18) and is covalently attached to a free thiol group of a cysteine residue resulting in a Sulfinic acid $\left(\mathrm{CH}_{3} \mathrm{SO}_{2}\right)$ leaving group. Native cysteines are used when present but it is necessary to create multiple single cysteine mutants in order to make distance measurements along the entire polypeptide chain. Native cysteines are mutated to alanines so that only one label can be attached at a time. Alanines are used because they are the most "average" of the amino acids. The
backbone resonance assignments for the orthologues are determined in aim 1.a. 1 and there should only be minor changes in the ${ }^{15} \mathrm{~N}$ HSQC spectra of the cysteine mutants when compared with the wild types, allowing residue assignment without the need for three dimensional spectra collection. Perturbations in the ${ }^{15} \mathrm{~N}$ HSQC spectra were used to estimate any disruptions in the structure upon introduction of the cysteine and/or the spin label. In general, structural disruptions are small and local.

Figure 18 - MTSL structure. a) The Sulfinic acid leaving group b) the disulfide bond that is broken upon reacting with the free thiol of a reduced cysteine $c$ ) Unpaired electron

The PRE intensity measurements are made by collecting a ${ }^{15} \mathrm{~N}$ HSQC spectra with the MTSL attached to the cysteine. The MTSL is then reduced with a 5 fold excess of ascorbic acid, and another spectrum is collected. Figure 19 illustrates the MTSL label's relaxation enhancement of the dog mutant C37A, S48C and the recovery of the resonance intensities following the addition of
ascorbic acid. The resonance intensity quotient, the peak intensity without ascorbic acid vs. the intensity with ascorbic acid, can be used to calculate the distance between the unpaired electron of the label and the amide proton.

Figure 19 - Paramagnetic Relaxation Enhancement. a) Shows the relaxation enhancement of the MTSL label on the resonances nearest the label i.e. missing resonances. b) Shows the recovery of the resonances nearest the label by reducing it with ascorbic acid.

PRE measurements were made on the dog, guinea pig, and mouse homologues (intensity ratios can be seen in Appendix C). These homologues were chosen because they span the range of ordered/most helical (guinea pig), least ordered/least helical (mouse), and most evolutionarily divergent (dog and mouse). Dog and mouse contain a native cysteine at residues 37 and 40, respectively, that was mutated to an alanine to allow the other constructs to be created, four additional cysteines variants were then generated selecting residues using the strategy proposed by Battiste (199). Their studies show that
polar or charged residues should be mutated, while non-polar residues should be avoided to maintain minimal structural perturbations. The mutations were also designed to be near the binding sites while hopefully not disturbing them and to spread them out across the polypeptide to get a global picture of interatomic distances.

In total there are four new cysteine variants for dog, five for guinea pig, and four for mouse. all using site directed mutagenesis and confirmed with sequencing. The dog mutations include E7C-C37A, E21C-C37A, C37A-S48C, and C37A-A65C. The cysteine mutants for guinea pig, and mouse include E7C, E28C, D41C, E56C, and E71C for guinea pig, and E11C-C40A, E32C-C40A, C40A-E64C, and C40A-E75C for mouse. Figure 20, Figure 21, and Figure 22 show the $I_{\text {ox }} / I_{\text {red }}$ quotient for all the dog, mouse, and guinea pig cysteine variants, respectively.

## Distance calculations.

In a very general way the quotient is indirectly proportional to the protonelectron distance. Distances will be calculated using an analytical approach developed by Dr. Kashtanov based on the formula presented by Battiste (199):

$$
\begin{gathered}
\text { The distance, } \mathrm{r}=\left(\mathrm{K}\left(4 \tau_{\mathrm{c}}+3 \tau_{\mathrm{c}} /\left(1+\omega_{\mathrm{h}}{ }^{2} \tau_{\mathrm{c}}{ }^{2}\right)\right) / \mathrm{R}_{2}^{\mathrm{sp}}\right)^{-6} \\
\text { Where, } \mathrm{K}=(1 / 15) \mathrm{S}(\mathrm{~S}+1) \gamma^{2} \mathrm{~g}^{2} \beta^{2}=1.23 \times 10-32 \mathrm{~cm}^{6} \mathrm{~s}^{-2} \\
\tau_{c}=3.3 \mathrm{~ns} \text { in our case or get from model free with } \mathrm{R}_{1} \text { and } \mathrm{R}_{2} \text { data } \\
\omega_{\mathrm{h}}=\text { proton Larmor frequency, get from the spectrometer }
\end{gathered}
$$

Figure 20-Oxidized/reduced intensity ratios for the paramagnetically labeled dog cysteine mutants.

Figure 21 - Oxidized/reduced intensity ratios for the paramagnetically labeled mouse cysteine mutants.

Figure 22 - Oxidized/reduced intensity ratios for the paramagnetically labeled guinea pig cysteine mutants.

$$
\begin{align*}
& \mathrm{R}_{2}^{\text {sp }}=\text { get from the next equation: } \\
& \mathrm{I}_{\text {ox }} / I_{\text {red }}=\mathrm{R}_{2} \exp \left(-\mathrm{R}_{2}^{\text {sp }} \mathrm{t}\right) /\left(\mathrm{R}_{2}+\mathrm{R}_{2}^{\text {sp }}\right) \tag{2}
\end{align*}
$$

In which, $I_{\text {ox }} / I_{\text {red }}$ is the peak intensity ratio between two spectra $\mathrm{t}=9.7 \mathrm{~ms}$, for the gNhsqc sequence
$R_{2}$ is the proton transverse relaxation rate of the unlabeled protein

Longitudinal and transversal relaxation rates were collected for the homologues subjected to PRE, these relaxation rates were used to estimate the Tc in the distance calculations. They also give corroborating evidence on the backbone flexibility, but as seen above Figure 16 are not as sensitive as the NHNOE measurements, the T1 and T2 data can be seen in Appendix B. The calculated distances for guinea pig are presented in Figure 25, the distances for dog, and mouse can be found in Appendix B. Using native cysteines as well as cysteine mutants introduced by site directed mutagenesis each of the three homologues were measured with 5 label positions in the sequence, yielding 5 distance restraints for each assigned non-proline residue of each homologue for a total of over 1000 distance restraints. The T1 and T2 times were calculated by fitting the relaxation rates for each residues' intensity. As can be seen in Figure 25 the distances from the electron range from about 10 Angstroms up to 25 Angstroms.

Visual examination of the calculated distances in Figure 23, Figure 24, and Figure 25 immediately reveals a non-random distance distribution. Indeed there appears to be possibly three regions that are closer to one another than a random coil would present, these essentially represent the $\mathrm{Mdm2} / \mathrm{MdmX}$ binding
site, the putative RPA70 binding site, and then a region just after the RPA70 site and just before the polyprolyl domain. Additionally it is apparent that guinea pig is the most collapsed of the homologues measured here. This is consistent with the secondary chemical shifts and the small angle x-ray scattering analysis (see chapter 3). The distances show a more complicated picture where residue 11 is nearer several regions than a random coil would be, but especially near to the region around 45. Residue 28 also shows some proximity to several regions across the sequence, while residue 41 displays a clear proximity to regions near $16,20,32,63$ and 77 . These are contacts are supported by the other two mutants, E56C, and E71C. These results are compatible with the proportionate structural and dynamic propensities observed in the $\Delta \delta$ and NHNOE plots.

# Chapter Three - The Evolution of Structure and Dynamics of p53TAD Homologues ${ }^{2}$ 

## Rationale

Evolutionary studies on compact ordered proteins revealed that proteins with as low as $30 \%$ sequence identity often have nearly identical folds and identical functions, whereas IDPs often have lower sequence identity than expected even with known functional homologues (149-153). A number of studies have concluded that disordered proteins generally evolve faster than their ordered counterparts. This behavior is thought to be related to the weaker structural constraints imposed upon IDPs (92-94, 201-204). Nevertheless, there are only a couple of studies that have directly analyzed and compared the impact of this rapid evolution on the structure and dynamics of IDP families $(96,205)$. In contrast, there have been many case studies, and several systematic studies on the conservation of structure and dynamics in ordered proteins (206-210).

A previous study found that the dynamic behavior for a family of intrinsically disordered linker domains was conserved in the face of negligible amino acid sequence conservation (96). This study represented the first

[^3]experimental test of the evolutionary conservation of dynamic behavior for a family of IDPs and demonstrated that amino acid sequence conservation was not required for the conservation of dynamic behavior and presumably molecular function. The intrinsically disordered linker domains used in the previous study acted as a simple tether between two ordered domains and did not have any known binding partners. This is a commonly observed phenomenon of IDPs. Another commonly observed phenomenon of IDPs is that they often fold upon binding to various ligands be it protein or DNA (79, 211-213). In particular, many IDPs form amphipathic helices when they bind to other proteins. The transactivation domain of the tumor suppressor p53 (p53TAD) is an example of an IDP that forms an amphipathic helix when it binds to Mdm2 or RPA70 (45, 77, 214-216).

Previous NMR spectroscopy studies of human p53TAD identified transient secondary structure in the Mdm2 and RPA70 binding sites $(214,216)$. This is a common observation for IDPs that fold when they bind to another protein (52, 79, $211,213,217,218)$. It is expected that the amount of transient helical structure in the free IDP may be conserved for a particular IDP family if these regions are important for function. However, a direct test of this hypothesis has not been performed.

In the current study, p53TAD was chosen as a model to test the relationship between sequence identity and structural similarity for a closely related family of IDPs that have multiple binding partners and undergo coupled folding and binding reactions with these partners. The p53TAD homologues
shown in Figure 8 have a range of sequence identities varying from 70\% between cow and rabbit down to $44 \%$ between dog and mouse. There is a high probability that the topology will be conserved when ordered proteins exhibit sequence identities in this range (149, 153, 219-223). NMR spectroscopy was used to measure the transient secondary structure and backbone dynamics for the p53TAD homologues shown in 8. NMR chemical shifts and backbone dynamics data of the p53TAD homologues were correlated with the sequence identity matrix.

## Transient Helical Secondary Structure

Figure 26 shows a surface image of Mdm2 residues 17-125 (gold structure) bound to a peptide corresponding to residues 15-29 of human p53 and a surface image of RPA70 residues 1-120 (green structure) bound to a peptide corresponding to residues $40-57$ of human p53. It is expected that the bound structures of the p53TAD homologues will be similar to the bound structures of the human homologue seen in Figure 26. This is a reasonable expectation, because their binding partners, Mdm2 and RPA70, are very highly conserved, and as such their binding clefts should be nearly identical. Indeed, the percent identity for the both the RPA70 and Mdm2 homologues is $85 \%$ or greater and there are no differences in the residues that make contact with p53TAD (data not shown).

Figure 26 - Surface images of Mdm2 (17-125) bound to residues 15-29 of human p53TAD is shown on the left, and on the right a surface image of RPA70 residues 1-120 bound to residues 41-59 of p53TAD is shown. PDB file 1YCR was used to generate the Mdm2 image and 2B3G was used to generate the RPA70 image (45, 77).

Chemical shifts for the backbone atoms of the p53TAD homologues were measured to examine their secondary structure propensities at single residue resolution. Figure 13 shows plots of the alpha carbon secondary chemical shifts $(C A \Delta \delta)$ for the p53TAD homologues. Shaded rectangles show the position of the Mdm2 and RPA70 binding sites. CA $\Delta \delta$ values are sensitive to phi and psi backbone dihedral angles and provide a reliable estimate of transient secondary structure for IDPs (176, 178, 224). Positive CA $\Delta \delta$ values are observed for residues in a helical conformation and negative values are observed for residues in a beta or extended conformation. Residue specific CA $\Delta \delta$ values for helical regions in ordered proteins range from 2-4 parts per million (ppm) (225). The smaller values observed in IDPs represent a population weighted average that can be used to estimate the \%helicity by dividing the $\Delta \delta$ of each residue by the
average $\Delta \delta$ of that same residue type when in confirmed alpha helix conformation (178). For instance, the \%helicity of the Mdm2 binding site in human p53TAD is about 11.9\% (calculated for residues 17-29). This value remains relatively constant for guinea pig (12.4\%) and rabbit (12.5\%) p53TAD and decreases for dog (5.7\%), cow (5.7\%), and mouse (3.4\%). Inspection of the sequence alignment in Figure 8 reveals that the Mdm2 binding sites (orange text in human sequence) are identical between human, guinea pig, and rabbit p53TAD but mouse, dog, and cow contain substitutions. For mouse, there is a glycine at position 21 compared to an aspartic acid for human while dog has two substitutions compared to human, a glutamic acid at position 21 and an asparagine at position 24 , and finally cow also has an asparagine at position 24 . The amino acid substitutions observed in the Mdm2 binding site of p53TAD occur on the solvent exposed side of the amphipathic helix (see Figure 26) and should not interfere with any contacts made by residues at the binding interface.

Figure 13 also shows variation in the transient helical structure of the RPA70 binding site. In particular, guinea pig shows a strong preference for helical structure with a \% helicity of 14.4\% (calculated for residues 40-57). Rabbit has the next highest value at $3.7 \%$. The $\%$ helicity values for human, mouse, cow, and dog p53TAD are close to zero. The sequences of the RPA70 binding site are more variable than the Mdm2 binding site. As mentioned above, it is assumed that all of the p53TAD homologues will adopt similar topologies when bound to RPA70. This assumption is based on the high degree of sequence conservation observed for the corresponding RPA70 homologues.

## Secondary structure predictors

In order to determine whether similar outputs are generated for the homologues, their amino acid sequences were analyzed using secondary structure prediction algorithms. The secondary structure prediction algorithms GOR IV and Jpred were used to analyze the sequences of the 6 p53TAD homologues $(226,227)$. Both algorithms successfully predicted some helical character in the Mdm2 and RPA70 binding sites. The Jpred algorithm had a tendency to predict the helix for the Mdm2 binding site 2-3 residues earlier than GOR IV. The CA $\Delta \delta$ plots show minimal helical character for these earlier residues. While both predictors were able to predict some helical character in the RPA70 binding site, there was little correlation in how extensive the helices would be. Neither predictor was able to reproduce the more extensive helical characteristics observed in the guinea pig RPA70 binding site. These two predictors do a reasonable job of finding regions of transient helical structure but are not able to accurately define the extent of the regions. Additionally, the predictor AGADIR was used to analyze these sequences; this predictor attempts to predict transient elements in solution, and gives a fractional output of each structural type for the overall sequence. The sequences of the full length polypeptides, as well as the isolated Mdm2 and RPA70 binding regions, were tested and yielded the poorest results of all the predictors(228). These results highlight the necessity of increasing the available database of experimentally confirmed structural and dynamic data of IDPs.

## Distribution of secondary structure types in the p53TAD homologues

The d2D method, developed by Vendruscolo and colleagues, was used to calculate the probabilities of three different secondary structure types from the backbone chemical shifts of the p53TAD homologues (229). Figure 27 shows the results from the d2D analysis of the p53TAD homologues. The probability for the alpha helix (blue bars), beta strand (red bars), and polyprolyl II helix (PPII) (green bars) secondary structure types are shown for all residues with chemical shift assignments. The remaining probabilities are in the random coil category. The sequences are shown along the x-axis and gaps are inserted based on a ClustalX alignment. Because the D2d method uses the chemical shifts from ${ }^{1} \mathrm{H}$, ${ }^{15} \mathrm{~N},{ }^{13} \mathrm{CO}$, and ${ }^{13} \mathrm{CB}$ in addition to the ${ }^{13} \mathrm{CA}$, it should provide a finer level of discrimination between the different secondary structure types than the CA $\Delta \delta$ analysis alone.

The data in Figure 27 shows more variation in secondary structure than would be expected based on the sequence identity between the homologues. Even the highly conserved Mdm2 binding site shows big differences. For instance, the human homologue has six residues in the Mdm2 binding site with an alpha helical probability between 0.09 and 0.30 while the mouse homologue has no residues in the Mdm2 binding site with an alpha helical probably greater than 0.02 . The RPA70 binding site shows more variation in secondary structure content than the Mdm2 binding site. This is consistent with the greater variation

Residue

Figure 27 - Distribution of secondary structure types for the p53TAD homologues. Probability of a particular secondary structure type is plotted on the y-axis for a) human, b) guinea pig, c) rabbit, d) cow, e) dog, and f) mouse. Data are shown for alpha helix (blue bars), beta strand (red bars), and PPII helix (green bars). The remaining probability is random coil.
in sequence identity for these regions but the differences cannot be explained based on this property alone. For instance, the sequence from L45W53 for the guinea pig homologue shows a strong alpha helical signal but this signal is completely missing in the rabbit homologue. This is interesting because the sequence identity of the RPA70 binding site for the two homologues is $63 \%$ and the most radical substitution in this region between the two is at residue 47. In guinea pig this residue is a proline while in rabbit it is an alanine. A proline would normally disrupt helical structure but in the guinea pig sequence the proline is in a position to aid in stabilizing an N-cap for the helix that forms when this region binds to RPA70. Also, the glutamic acid in position 49, has stronger helical proclivities than the aspartic acid in rabbit, this combination may explain why the helical signal for this homologue is so strong (230).

## Backbone dynamics

NMR spectroscopy was also used to investigate the backbone dynamics of the p53TAD homologues. Figure 17 shows plots of the amide ${ }^{1} \mathrm{H}-{ }^{15} \mathrm{~N}$ steadystate nuclear Overhauser effect (NHNOE). The NHNOE is sensitive to backbone motions on the nanosecond to picosecond timescale. This experiment is a reliable way to differentiate between ordered and disordered regions of a protein. NHNOE values for ordered proteins are positive and in the range of 0.8 , reflecting relatively slow rotational motion of a compact, globular polypeptide. For IDPs, NHNOE values can be positive or negative. Positive NHNOE values are usually observed in regions that have transient secondary structure and negative values are observed in more flexible regions. It is important to note that NHNOE
values will not be observed for proline residues due to their lack of an amide proton.

In general, there is reasonable agreement between the NHNOE values and the $\mathrm{CA} \Delta \delta$ values for the Mdm2 and RPA70 binding sites. Even the small changes in the transient helical structure of the Mdm2 binding site are detectable in the NHNOE data. The mouse homologue has smaller positive values in this region relative to human and the dog homologue only has two residues with positive NHNOE values that are significantly greater than 0.02 . The data presented in Figure 13 and Figure 17 provide a view of the evolution of structure and dynamics for a family of closely related IDPs at single residue resolution.

## Correlation and clustering analysis

Even though the secondary structure and dynamics of the homologues shows some apparent concordance, a more detailed comparison of this data with the sequence identity matrix of the homologues reveals that the dynamic behavior is more conserved than secondary structure. Pearson's $r^{2}$ correlation coefficient was used to compute pairwise correlation matrices for chemical shifts, NHNOEs, and secondary structure distributions (as determined by the d2D methodology), in order to test for similarities between the structural data and the sequence identity matrices of the homologues. The differences between these pairwise correlation matrices and the sequence identity matrices were determined by computing the Euclidian norm. Similarities between the structural data and the sequence identity matrices were also analyzed using a clustering
approach. Principal component analysis (PCA) was used in combination with fuzzy c-means. The general algorithm for FCM was used as follows [2]:
set the data $X$ with $n$ data vectors consisting of $d$ data points:

$$
X=x_{i j}, i=1 \ldots n, j=1 \ldots d
$$

set number of clusters: $2 \leq c \leq d$;
set degree of fuzziness: $w \in(1 ; \infty)$;
set the convergence threshold: $\delta$ (was used $10^{-6}$ );
initialize the partition matrix $U=u_{i j} \in[0 ; 1]$ with random values;
compute clusters' centers for each data vector:

$$
c_{i}=\frac{\sum_{j=1}^{d}\left(u_{i j}\right)^{w} x_{n j}}{\sum_{j=1}^{d}\left(u_{i j}\right)^{w}}, 1 \leq i \leq c
$$

compute distance matrix $D$ between centers using Euclidian norm and update partition matrix $U$ :

$$
u_{i j}=\frac{1}{\sum_{k=1}^{c}\left(\frac{D\left(c_{k}, x_{n j}\right)}{D\left(c_{i}, x_{n j}\right)}\right)^{\frac{2}{w-1}}}, 1 \leq i \leq c, 1 \leq j \leq d
$$

repeat steps and until convergence threshold is reached: $\| U_{\text {step }}-$

$$
U_{\text {step }-1} \| \leq \delta
$$

All calculations were performed in MATLAB.

## Correlating structure and dynamics with the sequence identity matrix

Pairwise correlation coefficients between the different homologues were calculated for the $C A \Delta \delta$ values, the chemical shifts of $C A$, beta carbon (CB), carbonyl carbon (CO), the amide nitrogen ( N ), and the amide proton ( NH ), the different secondary structure probabilities predicted by the d2D analysis, and the NHNOE values. This procedure results in a matrix of correlation coefficients for each chemical shift type, secondary structure category, or NHNOE data set that can be directly compared to the sequence identity matrix for the homologues.

For instance, the similarity between the correlation matrix for the NHNOE data from the homologues and the sequence identity matrix is shown in Figure 28. This figure shows the correlation coefficients for the NHNOE values below the diagonal and the correlation coefficients for the sequence identity values above the diagonal. In order to determine whether any of the experimental data sets reflect the phylogenetic relationships between the homologues, the Euclidian norms were computed between the correlation matrices and the percent identity matrix. Figure 28 shows a graph of these Euclidian norms. The Euclidian norm approaches zero as the correlation increases i.e. a lower value indicates a stronger correlation. According to this result, the backbone dynamics of the homologues is the data set with the highest similarity to the sequence identity matrix.

Figure 28 - Correlation analysis for p53TAD homologues. a) Comparisons between the sequence identity matrix and correlation matrix from aligned NHNOE data. The values for the sequence identity matrix are shown above the diagonal and the values $r^{2}$ of the NHNOE correlation matrix are shown below the diagonal. Values on the diagonal were omitted for clarity. b) Euclidian norms between the correlation matrices of the different chemical shifts, secondary structure probabilities predicted by D2d, and the NHNOE values.

## Evolutionary conservation of the backbone dynamics

In order to further examine whether backbone dynamics, or any other structural features are conserved, principal component analysis (PCA) and fuzzy means clustering was performed on each of the correlation matrices. The clustering analysis also suggests that the backbone dynamics of the p53TAD homologues have the closest relationship to the percent identity matrix. The data sets were clustered using the aligned sequences of the mammalian homologues. While there was some consistent clustering centered around the Mdm2 and RPA70 binding sites for the CA $\Delta \delta$ values, as well as the chemical shifts of $C A$, CB, CO, and $N$ (Appendix A), the NHNOE data showed the most consistent and
most extensive clusters Figure 29. Clustering of NHNOE data using the aligned sequences of mammalian homologues revealed regions of conserved dynamics, resulting in consistent clusters in the p53TAD sequence in the Mdm2 and RPA70 interaction sites as seen in Figure 29. Figure 29 shows the result of clustering the NHNOE data from the aligned mammalian sequences into 4, 5, 6, 8 and 10 clusters for aligned non-proline residues. Each color represents a cluster of residues, meaning the changes in the NHNOE value at that residue position changed in a similar manner between the homologues. If residues consistently cluster as the number of clusters increases then the correlation between the sequence and the NHNOE data is significant.

Figure 6a illustrates that consistent groups of clusters are clearly observable spanning residues $19,21-24$ (I), 41,42,44,50 (II), 48,51,52,53 (III). As can be seen in Figure 6b which corresponds to the 10 cluster breakdown, group I (highlighted in red) is located within the Mdm2 interaction site, while groups II (highlighted in yellow), and III (highlighted in red) are located in the interaction site of RPA70. This indicates the presence of two discrete groups of p53TAD residues interacting with RPA70. This behavior is typical for all homologues and thus preserved by evolution. Backbone dynamics of the residues in groups I and III are similar and so cluster together. The backbone dynamics of group II shows little similarity with groups I and III. The rest of the residues are more randomly clustered.

Figure 29 - Clustering analysis of the aligned NHNOE data. a) Clustering of the aligned non-proline residues into 4,5,6,8,and 10 clusters. Each color represents a distinct cluster. Residue numbers correspond to human p53TAD sequence. b) Aligned sequences of mammalian homologues. Residues that cluster together within Mdm2 and RPA70 binding sites are highlighted.

The Mdm2 binding site is commonly considered as the region from residue 17 to 29 however, our clustering analysis outlines a narrower range spanning residues $19-24$ which is in agreement with the NHNOE plots shown in Figure 17. These are the residues that fit into the binding pocket of Mdm2 as depicted in Figure 30. In general the Mdm2 binding site is well conserved Figure 8. Nevertheless, there are notable differences in residues spanning 19-24.

Residues at positions 21, for dog and mouse, and 24 , for dog and cow, are substituted relative to the consensus. Despite these differences, the NHNOE
data for these residues still clusters with the other residues in this range. It is reasonable to conclude that the backbone dynamics of this region is conserved for mammals even though some of the sites vary over time. It is also worth mentioning that these residues (21 and 24) do not interact with Mdm2 directly but are still important for helix formation. Conversely, the clustering analysis shows that the backbone dynamics for residue S 20 is not the same as the other residues that interact with Mdm2 even though this residue is conserved.

The crystal structure of the human p53TAD/RPA70 complex revealed the existence of two helical regions on p53TAD, referred to as H 1 and H 2 . Helix H 2 is deeply embedded into the binding pocket and it plays an important role in the formation of the p53/RPA70 interface(231). Our clustering analysis supports this conclusion. Residues that belong to group III $(48,51,52,53)$ reside in the same cluster as residues that interact with Mdm2 from group I, which are also found to be deeply embedded when bound and are crucial for the p53-Mdm2 interaction. The group III residues are also more conserved than the group II residues, and the residues outside both binding sites, though it is still not as well conserved as the Mdm2 binding site. In the human p53TAD sequence this group contains residues D48, E51, Q52, and W53. Their position on helix H 2 is depicted in red in Figure 30. It has already been reported that E51 and W53 in p53TAD stabilize the orientation of the H 2 helix in the cleft of RPA70. Strong electrostatic interactions between D48 of p 53 and K88 of RPA70 also stabilizes the H 2 helix in the binding cleft of RPA70(77).

Figure 30 - Structures of human p53/Mdm2 and p53/RPA70 complexes. Residues of human p53TAD which cluster together and fall within the binding site are highlighted in in Red and Orange according to their clustering from Figure 29. Binding pockets of both Mdm2 and RPA70 are shown as surface areas with blue color. Known sites of specific p53TAD interaction in RPA70 are highlighted in yellow the loop containing K88 from RPA70 is marked in brown.

Helix H1 aligns with group II (residues 41,42,44, and 50) and clusters separately from H 2 , meaning its backbone dynamics do not correlate with the sequence variation in the same manner, but it is still conserved amongst the homologues. Previous NMR studies investigating p53TAD and RPA70 binding suggest that H 1 plays a secondary role in the interaction (231). The disparity in the backbone dynamics detected in our clustering analysis supports this proposed difference in functional behavior as seen in Figure 29. Positions of the residues in cluster II (D41,D42, M44 and 150) from the human sequence are shown on Figure 30 with light brown color. Although H1 plays a more secondary role in p53/RPA70 binding, altering the electrostatic interactions with RPA70, can still disrupt complex formation $(45,77)$.

## Correlating Backbone Dynamics and Disorder Probabilities

Looking at the backbone dynamics (Figure 17) and the disorder plots (Figure 9) an apparent correlation can be seen between regions of decreased flexibility and dips in the disorder predictions. This correlation between observed backbone flexibility and disorder probability has been noted before (232-234) Though none of the previous studies compared evolutionary related proteins, or tried to determine how accurately the predictors might predict backbone dynamics.

## The predictors.

A number of algorithms have been developed to identify IDPs and distinguish them from ordered proteins. This is achieved using the compositional differences in the amino acid sequences observed between ordered and disordered proteins (11-14). These algorithms can identify disordered regions that are 30 amino acids or longer with $75-80 \%$ accuracy, but it is unclear whether they provide any information about backbone dynamics at the level of single amino acid residues.

Three popular disorder predictors, VL-XT (www.pondr.com), IUPred (iupred.enzim.hu), and VSL2B (ist.temple.edu) were selected to test the relationship between disorder probability and backbone dynamics. These algorithms were selected because they predict disorder using different principles. The VL-XT predictor integrates three feed-forward neural network predictors (NNP). One NNP was trained using 8 long disordered regions identified from
missing electron density in x-ray crystallographic studies, and 7 long disordered regions characterized by nuclear magnetic resonance (NMR) spectroscopy (14). The other two NNPs were also trained using missing electron density from x-ray crystallographic data (235). For these NNPs, N- and C-terminal disordered regions of 5 or more amino acids were used in the training set. The abbreviation, VL-XT, stands for the use of Various methods to characterize Long disordered regions combined with Terminal disordered regions that were characterized using X-ray crystallography. When making predictions, VL-XT gives an output between 0 and 1 that is smoothed over a sliding window of 9 amino acids. If a residue value exceeds or matches a threshold of 0.5 the residue is considered disordered.

IUPred is an abbreviation for Intrinsically Unstructured protein Predictor. This algorithm distinguishes ordered regions from disordered regions by estimating pairwise interaction energies. This interaction energy is determined using amino acid composition, the local sequence environment, and potential intramolecular interaction partners. When predicting long disordered regions, IUPred calculates interaction energies over a 100 residue sequential neighborhood. IUPred also provides an output that varies between 0 and 1 with a threshold for the transition between order and disorder of $0.5(113,236)$.

VSL2B was also considered, it is a disorder prediction algorithm developed by the same group that developed VL-XT (237, 238). VSL2B stands for Various Short Long predictor and is the second version of VSL, and B denotes that it does not include the PSI-BLAST feature set. VSL2B was
developed using a larger database of experimentally characterized IDPs than VLXT, it incorporates 26 sequence-based features, including secondary structure prediction. VSL2B is more accurate than VL-XT at predicting short disordered regions; it accomplishes this by having a two tiered prediction method with separate prediction mechanisms for long or short disordered regions that are then combined by a Meta predictor $(239,240)$. VSL2B also provides an output scale from 0 to 1 with 1 being most disordered with a disorder threshold of 0.5 . All of these predictors do a good job making a gross distinction between the ordered and disordered regions in proteins, but it remains unclear if the variation observed in the prediction values has any relationship to the backbone dynamics of individual amino acids.

## Flexibility normalization.

NHNOE values for human, dog, mouse, cow, guinea pig, and rabbit p53TAD converted to NHNOE* values by taking the antilog and normalizing to 1 . This results in a range from 0 and 1 , with 0 corresponding to the most flexible residues and 1 corresponding to the least flexible. This number was then correlated with the predicted disorder scores from three sequence dependent disorder predictors. Significant correlations would be proof that the dynamic behavior of an IDP can be predicted by sequence analysis. Visual inspection of the plots in Figure 32 reveals strong negative correlations in all six homologues between the NHNOE* and the disorder probabilities for the Mdm2 binding. As mentioned earlier this region forms transient helical structure in the absence of Mdm2, which would increase the local rotational correlation time, resulting in
higher NHNOE*(45, 46, 241). The NHNOE* values for the six homologues show a peak in this region, consistent with previous observations of transient helical. The data presented suggest that VL-XT, IUPred, and VSL2B are sensitive to regions of reduced flexibility in IDPs.

## Regression analysis.

Linear regression analysis was performed on the NHNOE* and disorder probabilities to assess the statistical significance of the correlations observed in Figure 31. Correlation coefficients and two-tailed $p$-values for the linear regression were calculated. The correlation plots for the best fitting predictor of each of the homologues are shown in Figure 32. All the p-values were found to be less than 0.002 and in most cases were less than 0.0001 , indicating the correlations are significant. While these three predictors were specifically designed to identify long disordered regions they appear to also accurately estimate the backbone dynamics of individual amino acids in these long disordered regions.

## Residue specific accuracy.

Figure 33 shows the relative percentages for amino acid residues with VL-XT, IUPred, or VSL2B values that were $\geq 1 \sigma$ from the mean value estimated using the linear regression equations. The range of mean probability values $\geq 1 \sigma$ for all amino acids of each predictor is $21.6 \%$ to $28.7 \%$. Only the $A, E, L$, and $V$ residues were above this average for all three predictors, indicating that the

Figure 31 - NHNOE* and Disorder probabilities smoothed over a 5 residue window. (a) Human, (b) Dog, (c) Mouse, (d) Cow, (e) Guinea Pig, and (f) Rabbit p53TAD.

Figure 32 - Correlation Plots of the Best fitting plots for Human IUPred. (a), Dog VL-XT (b), Mouse IUPred (c), Cow VL-XT (d), Guinea Pig VSL2b (e), and Rabbit VSL2b (f).
predictors do a comparably poor job predicting the dynamic behavior for these residue types. $A$ and $E$ residues are predicted to be less ordered than they actually are. Conversely L and V are predicted to be more ordered than they actually are. L , and V were previously classified as order-promoting residues based on their low frequency of occurrence in a database of experimentally characterized disordered proteins (18). While A was classified as a neutral amino acid, and E was classified as a disorder promoting residue. L was the most frequently mis-predicted with over $75 \%$ of the disorder probabilities being $\geq 1 \sigma$ from the mean. The high frequency $-90 \%$ higher than the database
mentioned earlier - of an order-promoting residue may account for VL-XT, VSL2B, and IUPred inaccurately predict L residues' dynamic behavior in these p53TAD sequences.

Figure 33 - Relative percentage of incorrect predictions for VL-XT, IUPred, and VSL2B. An incorrect prediction is defined as a VL-XT, IUPred, or VSL2B value that is at least $1 \geq \sigma$ from the mean value estimated using the linear regression equations.

## Small Angle X-Ray Scattering

SAXS involves passing an intense beam of X-rays through a sample and measuring the deflection of the beam caused by that sample. Although SAXS yields a lower resolution "picture" of the system than X-ray crystallography does, it does not require a crystal and so is applicable for studying IDPs. SAXS is one of the few techniques that yields structural information about flexible macromolecules like IDPS. It gives a comprehensive picture of the ensemble including the degree of compactness of the macromolecule and the intermolecular distances within the solution. In this study SAXS will be carried out by Dr. Veronique Receveur-Brechot at the Architecture et Fonction des Macromolecules Biologiques in Marseilles, France. The analysis will include the
use of the Guinier approximation for information about the radius of gyration and the underlying distribution of molecular compactness. This can be used to test the validity of the ensembles generated by BEGR. The equivalent Guinier approximation resulting from a SAXS experiment can be simulated using the BEGR ensembles and can then be compared to the experimental plot.

## Sample preparation and conditions

SAXS experiments are conducted by Dr. Veronique Receveur-Brechot at the Architecture et Fonction des Macromolécules Biologiques in Marseilles, France. Unlabeled samples are expressed, purified and prepared as described previously, then concentrated to a final concentration of $10 \mathrm{mg} / \mathrm{mL}$ and then shipped to Dr. Veronique Receveur-Brechot for SAXS measurements.

## Radius of gyration.

The Guinier approximation from the SAXS data will give the average radius of gyration $R_{g}$ and the population of the protein that exhibits that $R_{g} . R_{g}$ describes the distribution of a polymer's mass about its center of mass, essentially describing how compact, or collapsed the polymer is about its center. This parameter may be used to reweight protein ensembles. The Rg of the Human, guinea pig, rabbit, mouse and dog homologues can be seen in Table 1, because our constructs are not all the same length we generated random ensembles as described in Chapter 5, creating unweighted pools of 10000 random structures and calculating the population weighted average $R_{g}$ of the pools as a normalization control.

Table 1 - Radius of gyration

| Protein | Residues | Prolines | Charge (@pH7) | $R C R_{g}$ <br> (Angstroms) | $\operatorname{Exp} \mathrm{R}_{\mathrm{g}}$ <br> (Angstroms) | $\begin{gathered} \left(\operatorname{Exp} R_{g}\right) \\ I^{*}\left(R C R_{g}\right) \end{gathered}$ |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| Human | 77 | 13 | -14 | 24.1 | $28 \pm .3$ | 1.16 |
| All P to A | 76 | 0 | -14 | 23.4 | $29 \pm .3$ | 1.12 |
| K24N | 77 | 13 | -15 | 24.2 | $26.3 \pm .6$ | 1.20 |
| Guinea pig | 92 | 13 | -14 | 26.0 | $30.3 \pm .2$ | 1.16 |
| Rabbit | 91 | 14 | -14 | 26.1 | $31.9 \pm .6$ | 1.22 |
| Mouse | 88 | 13 | -14 | 25.9 | $31.3 \pm .5$ | 1.20 |
| Dog | 81 | 11 | -15 | 24.7 | $32.2 \pm .3$ | 1.30 |

As can be seen in Table 1, all the homologues are in fact more extended than the random coil ensembles are. Human, along with guinea pig proved to be the most compact of the homologues with dog being the most extended. These results are compatible with the $\Delta \delta$ and NHNOEs seen in Figure 13 and Figure 17 , with dog being most flexible and having some of the smallest $\Delta \delta$, while human and guinea pig have some of the strongest $\Delta \delta$ and are also two of the least flexible homologues, the PRE experiments (Figure 23, Figure 24, and Figure 25) also confirm that guinea pig is more collapsed than the dog or mouse homologues. The dog and mouse homologues might be expected to have a more similar $R_{g}$ than is observed.

An explanation for the highly extended behavior of all the homologues can be explained by the abundance of the prolines and the high negative charges.

The K24N (the substitution found in dog) and all P to A mutants of human were created so the effects of this can be seen. The prolines contribute to the increased extension, but the charge repulsion may have an even stronger impact. The K24N substitution in dog or K24G substitution in mouse may also have an increased impact on the protein's compactness because, when bound by Mdm2 K24 in human is well positioned to form a hydrogen bond with S20, and a salt bridge with D21.

Figure 34 - p53 peptide bound by Mdm2. K24, S20 D21 highlighted to illustrate positioning Structure from 1YCR (45).

# Chapter Four - Effects of Structure and Dynamics on p53TAD Function 

## Modulating Structure, Dynamics and Binding Affinity of p53TAD

## Varying structure and dynamics

Examining the sequences in Figure 8, we made the observation that the prolines flanking the Mdm2 binding site were conserved. We expanded our alignment to see how conserved they were over a longer evolutionary time period, and found that these flanking prolines are conserved from frogs (Xenopus) through to human (Figure 35). The evolutionary distance needed to be extended out to bony fish (Oncorhynchus) before the down-sequence proline was lost. Given that prolines disrupt alpha helices and that the Mdm2 binding site shows transient alpha helix characteristics, we hypothesized that loss of these prolines would increase the helical propensities of the Mdm2 binding site. To test this we mutated the flanking prolines to alanines in wt human p53, and used NMR to measure their resulting transient secondary structure and backbone dynamics.

$)^{\sim 28 \%}$

Figure 35 - Alignment of p53TAD from multiple vertebrate species(for residues aligning with human 1-73). The prolines (in red) flanking the Mdm2 binding region (grey shading) are conserved. The Mdm2 binding region of human p53TAD shows alpha helical propensities for approximately $\mathbf{2 8 \%}$ of the molecular population.

Transient helical secondary structure population distributions for wt and the proline mutants were estimated from chemical shifts using the d2D method once again (242). Because the Mdm2 binding region adopts a stable $\alpha$-helical structure upon binding to Mdm2, we focused the d2D analysis on the fractional helicity for residues 15-30 (Figure 36). WT p53TAD had approximately $28 \%$ maximum $\alpha$-helical content in the Mdm2 binding region, which is consistent with previous reports using other means of estimating the structural content (Figure $36)(214,243)$. Mutating the N-terminal flanking prolines (P12,13A) resulted in a small increase in fractional helicity of the Mdm2 binding region, up to a maximum of approximately 32\%. Mutating the C-terminal flanking proline (P27A), resulted in a much greater increase in the $\alpha$-helical population, with the maximum value reaching approximately $64 \%$. Mutating all three of the flanking prolines (P3xA) and all 13 prolines of the p53TAD (PtoA) further increased the fractional helicity
to $66 \%$ and $84 \%$, respectively. Substituting alanines for prolines is expected to induce greater $\alpha$-helical propensities (244). It is important to note that the structural changes of the flanking mutants remained confined to the to the Mdm2 binding region and did not expand to other regions (Figure 37).

b

Figure 36 - Mutation of prolines systematically varies the $\alpha$-helical population distribution of p53TAD a) Amino acid sequences for residues 12-29 and maximal percent helicity values for WT p53TAD and proline mutants as calculated by the d2D method. b) $\alpha$-helical population distribution plots per residue of wt p53TAD and the mutants (aa 15-30).

Figure 37 - Transient helical secondary structure for wt p53TAD and the proline mutants. a) Alpha carbon secondary chemical shifts (CA $\Delta \delta$ ) and b) helical d2D plots for wt p53TAD (WT) and the proline mutants. CA $\Delta \delta$ values were calculated using the ncIDP (245). Red arrows indicate prolines positions.

As seen in Chapters 2 and 3 there was a general agreement between the transient secondary structure as assessed by $\Delta \delta$, and the D2d method, and the backbone flexibility as assessed by NHNOEs. To assess the effect that the prolines had on the backbone flexibility we measured the NHNOEs as described in Chapter 2. The observed changes in the backbone dynamics (Figure 38) reflects the changes seen in Figure 37 and support an associated loss of conformational flexibility for the P27A, P3xA, and PtoA mutants. Again the
effects of mutating the flanking prolines remained largely confined to the Mdm2 binding area.

Figure 38 - Backbone dynamics of helical mutants mirrors changes in transient secondary structure. NHNOE values for wt p53TAD and the proline mutants. The values shown are the average of three replicate experiments and error bars show one standard deviation.

## Increased binding between mutants and Mdm2

We further hypothesized that any increase in the helical population of the Mdm2 binding site would lead to increased binding affinity between Mdm2 and the p53TADs. We based this hypothesis on the assumption that greater helical content and reduced flexibility would decrease any entropic penalty associated with the binding between the ligands. Though how altering the conformational flexibility will affect binding affinity is not always that straight forward with IDPs (81, 246-249). To test what the effects the proline mutations have on binding affinity, we conducted isothermal titration calorimetry (ITC) experiments between the mutants and Mdm2.

The dissociation constant $K_{d}$ value for wt p53TAD binding to Mdm2 is consistent with previously reported $\mathrm{K}_{\mathrm{d}}$ values for p53TAD fragments (250-252). We found that mutating proline 27 to alanine causes tighter binding of p53TAD to Mdm2, the mutatioin results in 10-fold reduction in the $\mathrm{K}_{\mathrm{d}}$, which is also consistent with previous studies, where P27 was mutated to either alanine or serine (253, 254). However, mutating prolines 12 and 13 had a minor effect on the binding affinity, whether alone or with the P27A mutant. Mutating all the prolines increases the helical content of the entire polypeptide well beyond that of the P27A or P3XA mutants. This increase however, did not result in a commensurate increase in binding affinity compared with the increase from wt to P27A (Figure 39a). Therefore the binding affinity of Mdm2 to p53TAD is mainly correlated with the propensity of p 53 TAD to adopt a helical structure between residue 19 and 25 (Figure 39b).

Figure 39 - The free energy of binding ( $\Delta \mathrm{G}$ ) between p53 TAD and Mdm2. a) ITC data for WT, and the proline mutants, binding to Mdm2. B) The free energy of binding ( $\Delta \mathrm{G}$ ) between p53 TAD and Mdm2 is plotted versus \%helicity for wt p53TAD and the proline mutants. A smoothed line is drawn through the data points to emphasize the sigmoidal trend.

As a control to ensure that the changes to binding affinity were only associated with the structural and dynamic changes observed in the Mdm2 binding NHNOE measurements were performed on both p53TAD and P27A in the presence of a stoichiometric equivalent of unlabeled Mdm2. As seen in Figure 40 the differences in the backbone dynamics between P27A in complex with Mdm2, relative to wt p53TAD were mostly minor. This supports that the increased binding affinity is primarily the result of the reduced conformational flexibility and increased helicity of the Mdm2 binding region rather than any novel stabilizing contacts between Mdm2 P27A.

Figure 40 - Bound state helix of P27A does not extend beyond the Mdm2 binding site. NHNOE values for wt p53TAD (top plot) and P27A (bottom plot) in the presence of a stoichiometric equivalent of Mdm2. The position of proline residues is show with a $P$ and residues with resonances that have a very low intensity is the bound state have an * above the NHNOE value.

## Biological Impact of the Enhanced Binding Between p53 and Mdm2

Given that we can detect a significant increase in the binding affinity between p53TAD mutants and its negative regulator Mdm2 compared with wild type, we should see a biological impact. Because Mdm2 is a gene target of p53TAD, creating a negative feedback loop, the p53 response to DNA damage occurs in a series of discrete pulses. These pulses are regular and and their amplitude and duration are not found to be related to the amount of DNA damage
$(255,256)$. The number of pulses is however correlated with the amount of damage sustained, with greater damage resulting in more pulses. These pulses/cellular dynamics of p53 play an important role in controlling the cell's decision to repair the damage enter senescence, or undergo apoptosis (257). We hypothesized that the increased binding affinity between the p53 mutants and Mdm2 would disturb the dynamics of the p53 network, because the increased binding would lead to more rapid degradation of p53TAD, abbreviating the pulses. To test this hypothesis we collaborated with François Theillet ${ }^{3}$, Andrea Katzer ${ }^{4}$, Wanda Manieri ${ }^{5}$, Phillip Selenko ${ }^{3}$, Alexander Loewer ${ }^{4}$

## Summary of results

The results of this collaboration are as yet unpublished and so are not shown. It was found that the decreased dynamics of the proline mutants altered the dynamics of the p53 pulses following DNA damage assays. While the relative intensity of these pulses remained relatively consistent, the length of the pulses was shortened and the frequency of the pulses was increased as a function of increasing helicity. This is consistent with the increased binding affinity observed between p 53 and Mdm 2 as a result of this increased helicity. Mdm2 inhibitors were used as a control to confirm that it was the altered p53 to Mdm2 interaction that was responsible for these changes.

[^4]Upregulation of the downstream gene targets of p53 were then assayed to determine if the altered pulsatile dynamics had any effect on cellular function. The shortened pulses of p53 expression did result in lower levels of the target gene expression. To assess the impact of this altered expression profile, cell cycle progression following DNA damage was examined. The cells expressing the proline mutants were found to be less able to halt the cell cycle in the G1 phase following DNA damage. Therefore the tighter binding of the mutant p53 to Mdm2 ultimately results in the abrogation of p53's ability to influence cell fate

## Chapter Five - Structural Ensemble Generation

## Rationale

Fully identifying the distribution of structures that make up the naturally occurring ensemble of an IDP is a significant challenge in structural biology $(2,8$, $30,258,259$ ). Several groups have proposed methodologies that produce structural ensembles that are consistent with their experimental data, however, it remains unclear whether any of these methods are producing naturally occurring structures (31, 33, 34, 38, 39, 243, 258, 260-271). One of the primary challenges for IDP ensemble generators is the uniqueness problem. It is well established that the conformational space available to even a small IDP is massively large. So large in fact, that it is impossible to make enough unique experimental measurements to avoid an underdetermined solution where seemingly unrelated, independent structural ensembles fit the experimental data equally well (258).

The approach that is presented here depends on a broad sampling of conformational space to generate large and diverse ensembles of structures. Increasing the size and diversity of the pool used to fit the data may help mitigate the uniqueness problem by increasing the probability that the pool will contain naturally occurring structures. These structures will then be subjected to a reweighting scheme that selects a subset of structures that are best able to reproduce the experimental measurements. While the approach does generate
conformational ensembles that provide suitable fits to the experimental data, it is important to consider these ensembles as one of many possible representations of reality.

The method of ensemble generation is still under development and so only a selection of the homologues have been processed using the CA $\Delta \delta$ as an example of the progress made. The homologues selected span a relatively broad range of similarities, with identities as low as $56 \%$, but with regions of increased identities in known binding sites, see (Figure 8)Error! Reference source not found.. The homologues processed for this chapter include the human, dog, and guinea pig homologues. The dog is one of the most flexible IDPs here, while guinea pig was selected for being one of the most structured (see Chapter 3). In addition to these homologues the P27A mutant of human was also selected because of its increased helicity in the Mdm2 binding site resulting from this single mutation (see Chapter 4).

## Broad Ensemble Generator with Re-weighting

The broad ensemble generator with reweighting (BEGR) begins by creating a large pool of structures using computer simulation. The BEGR methodology is under development by Stepan Kashtanov Ph.D. in collaboration with Marty Ytreberg Ph.D ${ }^{6}$. The pools presented in this Chapter comprise with one million structures each. These structures were generated using the trajectory directed ensemble-sampling (TraDES) software (272). TraDES uses a

[^5]build-up method to generate structures, utilizing energy terms to guide the buildup process. Most sampling techniques, like molecular dynamics or Metropolis Monte Carlo simulations have the potential drawback of oversampling local energy minima. Build-up techniques like TraDES avoid this by generating every structure from scratch. The TraDES software was set so that the structures generated should not be biased toward any secondary structure - essentially they should be close to a random coil state.

## Reweighting

The next step is to calculate what experimental values would be for each candidate structure in the entire pool, for example backbone $\delta$, RDC, or SAXS data. Alpha carbon chemical shift values can be calculated for each of the one million structures in the pool using SPARTA+(273). Other programs may be used in the future for the other structural measurements, like CRYSOL may be used for calculating the corresponding SAXS spectrum $(274,275)$. All the pools shown in this chapter are reweighted against alpha carbon $\Delta \delta$. To account for experimental error the Gaussian random noise was added to the experimental data.

The best fit is found by assigning each structure within the pool a weight such that the weighted average of the calculated data most closely resembles the experimental data. This weight represents the importance of a specific structure in fitting the data, it is not however a direct representation of how likely that specific structure actually occurs in nature. These weights are assigned by
optimizing the fit between the weighted average of the ensemble and the experimental data. Mathematically this corresponds to minimizing the two-norm of the difference between the experimental spectrum and the weighted average simulated spectrum:

$$
\min _{\mathbf{w}}\left\|\boldsymbol{I}^{\operatorname{sim}} \cdot \boldsymbol{w}-\boldsymbol{I}^{\exp }\right\|_{2}^{2}, \text { where } w_{i} \geq 0 \text { and } \sum_{i=1}^{N} w_{i}=1
$$

Where $\boldsymbol{w}$ is the vector of $N \times 1$ structure weights $w_{i}$ must all be positive, and $N$ is the number of structures to be re-weighted. $P^{e x p}$ is a $k x 1$ vector containing the experimental data where $k$ is the number of available experimental data points (number of available $\Delta \delta$ ). Finally, $\boldsymbol{I}^{s i m}$ is a $k x N$ matrix containing the simulated spectra, where each column in the matrix is a spectrum for a single structure from the pool.

## Using alpha carbon chemical shifts to reweight structural ensembles

CA chemical shifts were exclusively used for these examples because they have a simple relationship with the backbone dihedral angles phi and psi, and are more readily available for other proteins than the more difficult to measure RDCs or PREs, and because using only CA chemical shifts could represent the best minimalist approach to generating realistic structural ensembles of IDPs (177). For IDPs that are subject to coupled folding and binding, it is thought that the unbound protein will occasionally sample conformations that are similar to the bound structure(s) as in the conformational selection model, but there is no clearly established relationship between an
ensemble average property like the chemical shift and the frequency that structures similar to the bound state are sampled.

Figure 41 - Fitting the Broad Ensemble with noise. Correlation plots with the BEGR CA $\Delta \delta$ on the $Y$ axis as a function of the NMR experimental values. Green circles represent the $\Delta \delta$ of the unweighted ensemble CAs, the blue represents the weighted ensemble CA $\Delta \delta$ using $100 \%$ noise. The red line is added as a reference for a perfect correlation. These four fits are for one replica each, and are representative of the other two.

The CA $\Delta \delta$ for the orthologues and the some human mutants can be seen in Figure 13, and Figure 37, respectively. As previously discussed positive CA $\Delta \delta$ values indicate helical conformations and negative values indicate beta or extended conformations. As discussed in previous chapters the Mdm2 binding site of the p53TAD homologues (residues 17-29 in human) has some transient helical structure which can be increased significantly in a P27A mutant. There is
also a minimal amount of transient helical structure in the RPA70 binding site in most of the homologues, with the exception of the guinea pig construct which shows at least as much transient helical character as the Mdm2 binding site.

Using the BEGR approach three independent ensemble pools of one million each were created for the wt human, P27A mutant human, guinea pig, and dog sequences. The CA chemical shifts for each structure were calculated and then each structure's contribution to the final ensemble was weighted in order to best fit the experimental data, using 0.2 PPM experimental error and $100 \%$ noise for the ensemble structures. Figure 41 shows the quality of the resulting fit between the weighted ensembles and the experimental data using $100 \%$ noise. The green circles represent the unweighted ensemble CA $\Delta \delta$ as a function of the NMR experimental CA $\Delta \delta$. The blue circles represent the reweighted ensemble CA $\Delta \delta$ with noise as a function of the NMR experimental CA $\Delta \delta$, fits without the addition of noise can be seen in Appendix E. The red line represents a perfect correlation.

The incorporation of the noise greatly increases the size of the reweighted ensembles, without any noise addition the pools all contain 71 or fewer member structures. The reweighting of the one million member pools with noise taken into account yielded reweighted ensembles as follows: approximately 10480 members for each of the human wt ensembles, each of the P27A mutant ensembles were between 8690 and 9100 , the guinea pig were all between 10 245 and 10850 , and finally the dog ensembles were all between 10750 and 10 850 see Table 2.

Table 2 - BEGR Reweighting and Structural Alignment

## Reproducing Experimental Chemical Shifts and Convergence of Multiple Ensembles

Each panel in Figure 42 displays the calculated average fractional helicity of each residue for the three separate ensembles as calculated by STRIDE (276). It can be seen that the regions of increased helicity in the ensembles correspond to the regions of increased helicity in the experimental data, i.e. the Mdm2 and RPA70 binding sites. It is also important to note that this method is sensitive to the degree of fractional helicity in the experimental data as well. This can be seen in the decreased values seen in the Mdm2 binding region of the dog ensembles versus that of the human, or guinea pig. It is also important to note that the increased fractional helicity of the RPA70 binding site of guinea pig is well represented in all three ensembles. The BEGR method is even sensitive to the single amino acid change P27A, as there is a clear increase in the helical
content of the Mdm2 binding site of the P27A ensembles versus that of the wt human, while the rest of the P27A weighted ensemble structures maintained the lower helicity of the wt.

Figure 42 - Fractional Helicity of Reweighted Ensembles with noise. Each panel represents three separate one million pool ensembles reweighted using the CAD with $100 \%$ noise. The plots show the resulting average fractional of the weighted ensemble for each residue. The top left panel is for wt human, bottom left is for the single proline mutant P27A, top right is guinea pig, and bottom right is the dog. *NB The P27A panel is not on the same scale, the light blue line in the P27A panel shows the cutoff of the other panel's axis.

To obtain converged BEGR ensemble secondary structure properties the experimental error in the chemical shift measurements was incorporated into the re-weighting procedure (using Gaussian noise) and very large pools were used. Appendix E shows why this was necessary, increasing the noise decreases the
calculated fractional helicity but increases the agreement between the separate ensembles. This agreement can be seen in Figure 42 it can be seen that there is agreement between the three separate ensembles for each homologue or mutant. This demonstrates that the independent ensembles have converged secondary structures. This is important because, while this is not the first time that chemical shift values have been accurately estimated for an IDP using a simulated ensemble of structures, it is first time that convergence of transient secondary structure has been observed between multiple independent ensembles (269).

## Naturally occurring structures are present in the BEGR ensembles

Multiple groups have developed methods of generating structural ensembles that are consistent with the available experimental data. If any of these ensemble incorporate structures actually occurring in nature remains unverified (2, $8,30,259)$. Using BEGR we were able to identify a sub population within the ensemble that demonstrates structures consistent with those found in nature. More specifically we find a small population of structures that show the bound structure for the Mdm2 binding site for the residues 19-24.

The histograms in Figure 43 show the frequency of the structures from each of the three independent BEGR ensembles as a function of the root mean square difference (RMSD) of alpha carbon position for residues 19-24 of p53TAD bound to Mdm2. The RMSD comparisons were made between the individual p53TAD structures from the re-weighted ensembles and the structures of the

Figure 43 - RMSD plots of the ensembles vs the Mdm2 bound structures with noise. Each panel displays the frequency of a structure within the ensembles with the RMSD on the $x$ axis. The top left panel shows the three wt human, bottom left corresponds to the P27A mutant, the top right is the guinea pig, and the bottom right is for dog. Each panel shows all three ensembles in red, green and blue.
p53TAD peptides bound to Mdm2 (45). Only a very small population with RMSD values below 0.5 angstrom was considered to fit the bound structure. However all of the BEGR ensembles generated contained individual conformations that were similar to the structures of p53TAD peptides bound to Mdm2 (see Table 2), approximately 10 for each of the reweighted homologue ensembles even in the ensembles generated for dog, which showed the weakest helical content in the experimental data. Close inspection of the wt versus P27A histograms shows the expected trend where the weighted frequency of structures
with the lowest RMSD is higher, averaging about 16 for the mutant versus 10 for wt. This is not surprising because the P27A ensemble was re-weighted using the $\Delta \delta$ data representing greater transient helical structure. It is surprising however to find as many structures in the dog ensemble fitting the bound structure as observed in the human and guinea pig ensembles considering dog's transient secondary structure was much weaker.

The reweighted ensemble structures were also aligned with a human peptide bound to RPA70 (PDB ID: 2B3G) and their frequencies were plotted as a function RMSD in Figure 44. It is not surprising that there are far fewer structures with low RMSD values considering the far weaker $\Delta \delta$ values used to reweight this region. In fact there were no structures found to have RMSD values lower than 0.5 angstroms for the human, its mutant, or the dog ensembles. The guinea pig ensembles however were found to have one or two structures in this range. This pattern holds true even if the qualifications for a fit are relaxed to 1 angstrom RMSD, here the guinea pig ensembles contain between 20 and 30 fitting structures while the others all contain far fewer (Table 2). It may seem surprising that this value is so low considering the far stronger $\Delta \delta$ used for reweighting the guinea pig ensembles in this region, although this may be explained by the fact that the RPA70 binding site is comprised of two helices H 1 and H 2 , and not just one, like the Mdm 2 site, with H 2 being more stable than H 1 , with H 2 being the bound-like structure observed (231).

Figure 44 - RMSD plots of the ensembles vs the RPA70 bound structures with noise. Each panel displays the frequency of a structure within the ensembles with the RMSD on the $x$ axis. The top left panel shows the three wt human, bottom left corresponds to the P27A mutant, the top right is the guinea pig, and the bottom right is for dog. Each panel shows all three ensembles in red, green and blue.

Figure 45 displays overlays of the structures with the lowest RMSD between the reweighted structures in the ensemble and human p53TAD peptides bound to either Mdm2 or RPA70. In the top four panels the BEGR structures (shown in green) with the lowest RMSD for each of the four IDPs in this study is overlaid with the short peptides bound to Mdm2 (PDB ID: 1YCR). In the lowest panel the BEGR ensemble structures in green were overlaid with the short peptide bound to RPA70 in red (PDB ID: 2B3G).

Figure 45 - Overlays of the bound state structure of the p53 peptide bound to Mdm2 (1YCR) and the lowest RMSD BEGR structure are shown. RMSD between BEGR structures for p53TAD mutants and homologues and the bound state structure from the human p53TAD-Mdm2 complex (PDB ID: 1YCR). Bottom RMSD between Guinea pig BEGR structures for p53TAD and the bound state structure from the human p53TAD-RPA70 complex (PDB ID: 2B3G).

## Calculating root mean square deviation.

The root mean square deviations (RMSDs) between the experimental bound state structures (PDB ID 1YCR for MDM2 binding, and 2B3G for RPA70 binding) and the BEGR ensemble structures were determined using the g_rms program from the GROMACS 4.5 .5 software (277). The fit was determined using the alpha carbon atoms for the residues that were alpha helical, as predicted by STRIDE (276), in the experimental structure (residues 19-24 for 1YCR and 47-55 for 2B3G). The histograms were calculated by multiplying the RMSD values for the BEGR ensemble structures by their corresponding weight.

## Other/previous iterations

BEGR is still under development, and multiple methods have been utilized thus far to create the diverse pool of structures. A previously used approach that also uses a build-up model is worth mentioning. This method created the pool of candidate structures by using optimized side-chain geometries for each amino acid as the building blocks. Starting from the N -terminus of the sequence the first two amino acids are joined together using the randomly generated phi, and psi backbone dihedral angles then tested for any steric clashes - if there is a clash then a new set of bond angles are generated until there is no clash. This is repeated for every peptide bond in the chain until the C-terminal is reached. If an acceptable phi, and psi bond angle pair cannot be found in ten attempts then the previous amino acid's coordinates are regenerated, and the program looks for acceptable angles again. This is also retried ten times, if there is no resolving the
clash in ten attempts then the program goes back to regenerate the amino acids coordinates two residues prior to the current one and so on. This is repeated until a large pool of plausible structures is generated.

The pool of structures will then be further refined using molecular dynamics (MD) simulations to relax the structures and eliminate unphysical interactions. The simulations used GBSA implicit solvent and GROMACS 4.5.5 for these relaxation simulations, relying on the diverse ensemble set for the sampling of conformational space rather than the MD simulations(278, 279). The coordinates of the candidate structures are then converted into standard protein data bank (PDB) format for further analysis (280).

The candidate structures were then reweighted such that the weighted average of the calculated data has the best possible fit to the experimental data. In order to assign these weights, the fit between the weighted average of the pool's calculated figures and the experimental spectrum was optimized. Mathematically this corresponds to minimizing the following quantity:

$$
\chi^{2}=\frac{1}{k-1} \sum_{j=1}^{k}\left(\frac{I_{j}^{\text {sim }}-I_{j}^{\text {exp }}}{\sigma_{j}^{\text {exp }}}\right), \text { where } I_{j}^{\text {sim }}=\sum_{i=1}^{N} w_{i} \cdot I_{i, j}^{\text {sim }} \text { and } \sum_{i=1}^{N} w_{i}=1
$$

Where $N$ is the number of structures in the pool, $w_{i}$ is the weight of structure $l, k$ is the number of data points from the experimental spectrum, the experimental data points are $I_{j}^{\text {exp }}$ with error $\sigma_{j}^{\text {exp }}$ and the simulated spectra data points are $I_{j}^{\text {sim }}$. To minimize $\chi^{2}$ a Metropolis Monte Carlo simulated annealing approach was implemented. Simulations will be performed for a multitude of Monte Carlo
steps and the pseudo-temperature were lowered such that the temperature change decreases exponentially during the simulation. Trial moves consist of randomly changing a single $w_{i}$ value by $\pm 0.01 / N$.

## Chapter Six - Discussion

## Conservation of Structure/Dynamics of p53TAD

The evolution of transient secondary structure and backbone dynamics in a closely related family of IDPs was investigated using NMR spectroscopy. The p53TAD homologues showed variation in their secondary structure and dynamics that could be directly related to amino acid substitutions. In particular, the Mdm2 binding site of p53TAD was found to be highly conserved. Three of the homologues studied had substitutions in this region. These substitutions all occur on the solvent exposed side of the amphipathic helix that forms when p53TAD binds to Mdm2. However, the most common of these, K24N, does not appear to affect binding affinity (281). The transient secondary structure and dynamics for the RPA70 binding site showed more variability than the Mdm2 binding site and is consistent with the increased sequence variation observed for this region.

Clustering analysis of the NHNOE data revealed groups of residues that aligned well with helices that form when p53TAD is bound to either MDM2 or RPA70. Group I corresponded to the helix that forms when bound to MDM2. Groups II and III correspond to the H 1 , and H 2 helices that form when bound to RPA70, respectively. It is interesting to note that these groups flank notable phosphorylation sites S20, and S46. Phosphorylation of these sites is associated
with an apoptotic response to cellular stress $(124,282) . S 46$ is located in the loop region between H 1 and H 2 . The flexibility of this loop is important because it allows the backbone between the H 1 and H 2 helices to wrap around the binding pocket of RPA70. Conservation of the backbone dynamics for the residues surrounding phosphorylation sites may be necessary to maintain the phosphorylation-mediated damage response of p 53 .

It may be that the clusters represent local cooperative effects since they were observed in short regions corresponding to known binding sites that show measurable transient secondary structure. It is even tempting to make a connection between some long range cooperation between the clusters and prior evidence that the MDM2 and RPA70 binding regions make transient long-range contacts $(43,283)$. However, the data presented here are insufficient to make any definitive conclusions about this behavior.

Overall the clustering analysis shows greater divergence in the secondary structure data than expected based on sequence divergence. Nevertheless, strong correlations were found between the backbone dynamics and the sequence identity of the homologues. This result is consistent with a previous study from our group and suggests that the dynamic behavior of IDPs is a conserved evolutionary feature (96).

## Predicting Protein Dynamics

In Chapter 3, three popular algorithms for predicting disorder probability based on amino acid sequence were shown to accurately estimate the backbone
dynamics of individual amino acids in long disordered regions from a family of disordered proteins. These findings are consistent with the results from three previous studies, which observed correlations between backbone dynamics and disorder probability using either molecular dynamics simulations or NMR dynamics measurements. In one of these studies, increased internal flexibility was suggested by both disorder predictors and molecular dynamics simulations (232). In a second study, the insertion of a $\beta$-hairpin between two chimeric proteins resulted in a significant increase in predicted disorder probabilities that were subsequently confirmed using NMR dynamics measurements (233). The third study found a strong negative correlation between the degree of predicted disorder and the stability of the protein complexes. In the third study, molecular dynamics simulations were used to show that binding regions with higher predicted disorder probabilities correlated with weaker complex formation (234).

While the dataset used for this comparison is small, the correlations observed are robust, and demonstrates the accuracy of the disorder predictors for backbone dynamics at single amino acid resolution. As more experimental data on the backbone dynamics of IDPs is collected we predict this relationship will be refined so that in the future the NHNOE and other NMR measurements that provide information about residue specific structure and dynamics can be used to guide the development of disorder predictors.

## Effects of the Proline Mutants

In chapter four we demonstrated how altering an IDP's propensity to form transient helical secondary structure can affect binding affinities. Adding the unpublished data of our collaborators we can see that this altered binding affinity changes the dynamics of the p53 molecular network in response to insult. These altered dynamics of the p53 network impacts its ability to sufficiently upregulate its target genes, ultimately affecting the response to DNA damage, as the cells were found to be defective at the G1 checkpoint.

The binding affinity between p53 and Mdm2 was tuned by reducing the conformational flexibility of the binding site. The changes in binding affinity observed for the proline mutants $\mathrm{P} 27 \mathrm{~A}, \mathrm{P} 3 \times \mathrm{A}$, and PtoA correlate with the fractional helicity suggesting that any entropic penalty from the disorder-to-order transition has been reduced. Mutating the highly conserved P27 residue doubled the population of transient helical secondary structure of the Mdm2 binding site. Importantly, this increase remained localized to the Mdm2 binding site. This allowed us to alter binding affinities without changing functional groups or affecting modification sites. The fact that mutating a single residue has such a large impact on the transient helical secondary structure and binding affinity of the Mdm2 binding region, coupled with its conservation across mammals, birds, and amphibians (Figure 35), suggests the population of transient helical secondary structure in wt p53TAD has been finely tuned by evolution.

We hypothesized that this level of transient helical secondary structure sets a defined affinity for the binding to Mdm2 and is therefore necessary for the fidelity of the cell signaling response and network processing. P27's conservation in p53 throughout most vertebrates (Figure 35), and the fact that its mutation significantly reduces the p53's ability to activate transcription and arrest the cell cycle, supports the hypothesis that a more disordered structure is necessary for p53 to properly regulate the cellular response to DNA damage. Indeed, although rare, P27 mutations have been found in human cancers (284, 285).

This hypothesis was tested using transgenic cell lines expressing the various proline mutants. The altered binding affinity between p53 and Mdm2 was confirmed in vivo using the inhibitor Nutlin 3, which competes for the p53-Mdm2 interaction. This also indicates that the p53TAD dominates the overall affinity between p53 and Mdm2 even though there are additional contact sites (286, 287). The mutants were found to alter the dynamics of p53 accumulation in response to DNA damage. The pulses of p53 accumulation still occurred, they were simply shorter and had a higher frequency in the tighter binding mutants. This observation confirms a previous mathematical model of the p53-Mdm2 feedback loop in which one of the few criterion capable of disrupting the pulsatile dynamics was the p53-Mdm2 binding affinity (288).

The concentration dynamics of signaling molecules is integral to cellular information networking and decision making processes (289). It was previously reported that increasing the duration of p53 accumulation alters the resulting
expression profile of its target genes, affecting cellular fate (257). It was therefore hypothesized that, altering the dynamics of p53 accumulation would affect cellular fate, particularly that increased affinity for Mdm2 might lead to shorter pulsatile dynamics which would hamper p53 functionality. The experiments conducted support this hypothesis showing fewer cells caught in the G1 phase following DNA insult.

There are many other proteins that regulate p53 activity, including a few that bind to the same region as Mdm2, including the ATM kinase and the CBP acetylase (290-293). It is therefore likely that the binding affinities of these modifying enzymes were affected as well. This means that the altered dynamics and function of p53 may be some combination of elevated degradation and altered post-transcriptional modification levels. This extent of these other factors was estimated by measuring the phosphorylation and acetylation levels of ATM and CBP targets, respectively. The dynamics and levels of phosphorylation for the mutants were comparable with wt. The acetylation dynamics were likewise comparable, the acetylation levels however were altered, with the single mutant showing elevated acetylation levels compared with wt or the triple mutant. The reason for the increased acetylation could be due to higher affinities, though why the triple mutant returns to normal levels remains unclear. Despite the elevated modification levels observed for the P27A mutant, target gene expression showed little difference, indicating that the increased Mdm2-mediated degradation of p53 is the overriding contributor to the altered dynamics.

## Structural Ensembles

Our data show that the broad sampling of conformational space combined with re-weighting was capable of generating and identifying relevant structures that are known to exist in nature, even using a sparse experimental data set. It is highly unlikely that any of the full-length structures generated match any naturally occurring full length structures in nature at a given instant in time. However, given that we can find short segments it is likely that other short segments from the BEGR structures also exist in nature. Secondly it is interesting that we are able to find convergence of secondary structure in the ensembles and that we are able to find naturally occurring structural elements using just the CA $\Delta \delta$. This is significant because CA chemical shifts are relatively easy to collect and are therefore the structural data most readily available for IDPs. Based on this, the BEGR method should be able to make predictions about the location and structure of binding sites using just the CA $\Delta \delta$ of other IDPs. This may even be possible with proteins displaying weak transient secondary structure, as seen in the dog homologue. Finally our P27A data show that the BEGR method is sensitive to single amino acid changes that modify the average properties of the structural ensemble. This is exciting because determining how a disease related mutation affects the structural ensemble may create future drug discovery opportunities when targeting these IDPs.

## Concluding Statements

In this report we have shown that the dynamic behavior of this family of IDPs is more evolutionarily conserved than its secondary structure, which by inference highlights the importance of the dynamic behavior of this IDP family. The dynamics of these IDPs can be predicted with reasonable confidence within a protein's sequence using available disorder predictors, but refinement is necessary to compare the relative dynamics between separate proteins. We were able to rationally design mutants that perturbed the local structure and dynamic behavior of a binding site, increasing the binding affinity between the IDP and its ligand as a function of decreasing backbone flexibility and increasing fractional helicity. This change in affinity was then shown to affect the in vivo network dynamics ultimately altering the cellular fate.

We generated structural ensembles that not only reproduce bound structures using commonly available IDP data, but showed convergence in the secondary structure characteristics between independently generated ensembles, adding a degree of reproducibility to IDP ensemble generation that no one has been able to show heretofore. These reweighted ensembles were sensitive to single amino acid changes, increasing the number of structures within the ensemble that fit the Mdm2 bound structure. And while it's not surprising that increasing the transient helical content used to reweight the ensembles increase the number of structures fitting a bound helix, it is interesting that the reweighted ensemble with the lowest fractional helicity, the p53TAD from dog, had about equal the number of bound structure as the human or guinea pig
p53TAD ensembles. It is tempting to draw a connection to the ITC binding studies where a K24N mutant that shows far weaker fractional helicity than wt human (but close to that of dog), still showed similar binding affinity, while P27A shows increased affinity, and has increased fractional helicity and a higher number of bound-like structures in the reweighted ensembles (281). This similar binding compared with the low fractional helicity along with the observation that the small increase in fractional helicity of $\mathrm{P} 12,13 \mathrm{~A}$, which showed no significant change in the binding may indicate that there is a threshold of fractional helicity that must be crossed before any changes in the binding affinity is affected.

## Chapter Seven - Methods/Protocols

## Protein Purification and Sample Preparation

## Protein purification scheme

All orthologues were expressed using Novagen's pET Vector System, specifically pET28A plasmid seen in Figure 46. The vector encodes kanamycin resistance for selection and contains a T7 promoter followed by a six histidine tag, thrombin cleavage site, and multiple cloning site for expression, purification, and cloning purposes respectively. The plasmids are transformed into BL21 (DE3) chemically competent E. coli cells using standard heat shock and SOC recovery protocols.

## Transformation.

Transform $20 \mu$ l of BL21(DE3) cells from Novagen with 2 ng of plasmid

1. Incubate on ice for 5 min
2. Heat shock at $42^{\circ} \mathrm{C}$ for 30 sec
3. Cool on ice for 2 min
4. Add 125 ul of SOC (or NZY+) media
5. Incubate at $37^{\circ} \mathrm{C}$ for 1 hour with agitation (119pprox.. 225 rpm in shaker incubator)
6. Plate $25-50 \mathrm{ul}$ of this or 10 ul on one plate and the rest on another.
7. Incubate at $37^{\circ} \mathrm{C}$ overnight

The BL21(DE3) cells contain the gene for T7 polymerase under regulation of the lacUV5 promoter and so T7 polymerase expression can be induced by the addition of lactose or an analogue such as Isopropyl B-D-1thiogalactopyranoside (IPTG). This induction then results in amplified expression of any genes under control of the T7 promoter. All our sequences have been codon optimized and are inserted between the Nde I and Xho I restriction sites. The resulting constructs produce proteins with a 21 residue tag containing six consecutive histidine residues. Upon thrombin cleavage only 3 of the tags residues remain prior to the inserted sequence, specifically GSH.

## Expression and lysis.

The transformed E. coli cells are grown in M9 minimal media which allows for labeling the proteins produced with magnetically active nitrogen15, and/or magnetically active carbon 13 . The media is prepared to have a final composition as follows $6 \mathrm{~g} / \mathrm{L}$ of sodium phosphate dibasic, $3 \mathrm{~g} / \mathrm{L}$ of potassium phosphate monobasic $0.5 \mathrm{~g} / \mathrm{L}$ sodium chloride, 2 mM magnesium sulfate, $2 \mathrm{~g} / \mathrm{L}$ of dextrose (C13 labeled if necessary), 100uM calcium chloride, 10uM ferric chloride, $1 \mathrm{mg} / \mathrm{L}$ of thiamine hydrochloride, and $1 \mathrm{~g} / \mathrm{L}$ of ammonium chloride (N15

Figure 46 - pET28A vector. All sequences inserted between the Ndel and Xhol restriction sites.
labeled if necessary), with a final pH between 7.3 and 7.5 , the media is then filter sterilized and kanamycin is added to a final concentration of $30 \mathrm{mg} / \mathrm{L}$. Starter cultures are inoculated and allowed to grow for 14 to 16 hours at $37^{\circ} \mathrm{C}$ before the main culture is started at an OD of 0.02 - 0.04 absorbance units at 600 nm wavelength using a flow path of 10 mm . Optimal induction conditions are determined by inducing at varying temperatures and induction points i.e. when the OD reaches $0.4,0.6,0.8$ absorbance units. Samples are taken at preinduction points and periodically thereafter for SDS-PAGE analysis to determine
conditions necessary for maximum protein expression. The cells are pelleted by centrifugation at 11, 000 rcf for 20 minutes (multiple spins may be necessary depending on the size of the culture), the supernatant is discarded and the pellet is stored at $-80^{\circ} \mathrm{C}$ for no more than 1 month before purification.

Prepare M9 Media as follows:

Stock Salt solutions:

To make 1L of 10X M9 Salts:

Na2HPO4 60g

KH2PO4 30g
$\mathrm{NaCl} \quad 5 \mathrm{~g}$
pH to 7.1 with HCl bring to 1 L and filter Sterilize

1M MgSO4 Filter sterilized

20\% Dextrose Filter sterilized

50 mM CaCl 2 Filter sterilized
289.5 M FeCl 3 (in 0.1 M HCl to prevent precipitation)
$5 \mathrm{mg} / \mathrm{ml}$ Vitamin B1 Filter sterilized (Protect from light and store at $4^{\circ} \mathrm{C}$ )

To make 2 L of M9 Media, to 1.7 L of ddH 20 add (in this order more or less)
$\square \quad 200 \mathrm{~mL}$ of 10 x M9 salts
$\square \quad 4 \mathrm{~mL} 1 \mathrm{M} \mathrm{MgSO} 4$
$\square \quad 20 \mathrm{~mL}$ of $20 \%$ D-Glucose (alternately add 4 g of Dry D-Glucose)
$\square 4 \mathrm{~mL}$ of 50 mM CaCl 2
$\square 2 \mathrm{~mL} \mathrm{0.01M} \mathrm{FeCl} 3$
$\square$ 400uL of $5 \mathrm{mg} / \mathrm{mL}$ Vitamin B1
$\square \mathrm{pH}$ to 7.3-7.5 (toward the lower end reduces salt precipitation I adjust to 7.35)

Bring to 2 L with H 2 O and filter sterilize into 21 L bottles.

Growth and expression controls

Add 2 mL of M 9 media to Sterile test tube and label $-\mathrm{N}+$ Cells

Add 1 g of NH 4 Cl to one liter media, and shake

Add 2 mL of M 9 media +NH 4 Cl to new test tube labeled +N -Antibiotic + Cells

Add appropriate antibiotic: (pET28A is Kan resistant)

Kan=add 500 uL of $60 \mathrm{mg} / \mathrm{mL}$ to 1 L

Take $2 m L$ for control - label negative control

Inoculate $2 x 50 \mathrm{~mL}$ overnight startups with freshly transformaned colonies (one week or less is best)

Inoculate the first 2 controls

Place the remaining Media in the incubator overnight

## Expression

1. Measure OD@600nm (flow path of 1 cm ) of the overnight cultures (should be over 1.00)
2. Inoculate media to starting point of 0.02 OD
3. Monitor OD periodically (usually doubles every hour)
4. Induce culture with IPTG 1 mM final concentration (we usually mix the IPTG in Water just prior to induction then split it evenly)

Table 3 - Induction Times

| Protein | Wild Type | K24N | P27A | P12,13A | P12,13,27A | All P to A |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Induction <br> OD | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ | 0.8 |
| Induction <br> Time | 6 hours | 6 6ours | 6hours | 6 hours | 6 hours | 1 hour* |
| Protein | Dog | Mouse | Guinea <br> pig | Rabbit | Cow |  |
| Induction <br> OD | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ | $0.6-0.75$ |  |
| Induction <br> Time | 6hours | 4hours | 6hours | 6hours | 4hours |  |

1. Pellet culture at $11,000 \mathrm{~g}$ for 20 min each spin
2. Remove supernatant and Freeze pellet at $-80^{\circ} \mathrm{C}$

## Nickel and cobalt columns.

The cells are resuspended in 25 mL PBS buffer containing 10 mM imidazole and $0.02 \%$ sodium azide (NaN3) with protease inhibitors added. The resuspended cells are then lysed with a French pressure cell press. The French pressure cell press utilizes decompression and shearing stresses produced from compressing the cells to approximately 22000 PSI then rapidly decompressing them through a needle valve. This has advantages over other lysing methods like lysozyme and sonication because additional proteases or heat are not introduced to the system, which could degrade the protein of interest. The lysate is centrifuged at 38000 rcf for one hour to separate the soluble protein from other cellular components and any insoluble protein. This supernatant is passed through a 25 mL nickel column comprising NiNTA superflow resin from Qiagen using a fast protein liquid chromatography system like GE healthcare's AKTA system, the histidine tag binds to the nickel resin. The column is washed with three column volumes of lysis buffer, and then washed with three column volumes using a wash buffer containing 50 mM imidazole; finally the protein is eluted with the elution buffer which contains 250 mM imidazole. The eluate is fractionated based upon UV280 absorbance, fractions corresponding to higher UV absorbance are assayed using SDS-PAGE and only fractions containing a majority of the desired protein are pooled, concentrated and exchanged into gel filtration buffer (GFB), PBS buffered at pH 7, 0.02\% NaN, and 1 mM EDTA.

## Purification

Make Ni column Buffers for Non-Denaturing conditions

| 20\%Stock solution of Sodium Azide ( $\mathrm{NaN3}$ ) |  |
| :---: | :---: |
| 1L Lysis Buffer (A1)(You need about twice as much of this one as A2 or B) |  |
| To $\sim 800 \mathrm{~mL}$ of H 2 O add... |  |
| 50mM Sodium Phosphate Monobasic ( NaH 2 PO 4$)$ | 5.999 g |
| 300 mM Sodium Chloride( NaCl ) | 17.532g |
| 10mM Imidazole | 0.6808g |
| 0.02\% Sodium Azide (NaN3) | $1 \mathrm{~mL} / \mathrm{L}$ of $20 \% \mathrm{NaN} 3$ |
| pH to 8.00 and QS |  |
| 1L Wash Buffer (A2) |  |
| To $\sim 800 \mathrm{~mL}$ of H 2 O add... |  |
| 50 mM Sodium Phosphate Monobasic ( NaH 2 PO 4$)$ | 5.999g |
| 300 mM Sodium Chloride( NaCl ) | 17.532g |
| 50mM Imidazole | 3.404 g |
| 0.02\% Sodium Azide (NaN3) | $1 \mathrm{~mL} / \mathrm{L}$ of $20 \% \mathrm{NaN} 3$ |
| pH to 8.00 and QS |  |
| 1L Elution Buffer (B) |  |

- To $\sim 800 \mathrm{~mL}$ of H 2 O add...
- 50 mM Sodium Phosphate Monobasic (NaH2PO4)
- 300 mM Sodium Chloride( NaCl )
- 250 mM Imidazole
- 0.02\% Sodium Azide (NaN3)
- pH to 8.00 and QS

Also aliquot out protease inhibitors, we use P2714 from Sigma Aldrich

1. Resuspend pellet in 24 mL of Lysis buffer with one aliquot of protease inhibitors
2. Lyse cells (we use a French press keeping internal cell pressure about 20,000 psi)
3. Centrifuge lysate at $38,000 \mathrm{~g}$ for 1 hour
4. Run supernatant through Ni column

Table 4 - Nickel/Cobalt column program guidelines

| 5. Step | Equilibrate | Inject | Wash | Elute | Reequilibrate |
| :--- | :--- | :--- | :--- | :--- | :--- |
| Vol | 0.5 CV | $1.25^{*}$ Sample <br> Vol | 2 CV | 3 CV | 3 CV |
| Buffer | Lysis | Lysis | Wash | Elute | Lysis |

*A1, A2, and B refers to the Lines we use on our FPLC
** Our CV (Column Volume) is 30 mL of NiNTA fast flow Resin from Qiagen
We use a flow rate of 3 mL per min for the entire run
6. Run a gel of the peaks seen on the chromatogram and pool the fractions containing the protein of interest
7. Concentrate pooled fractions to a volume of 8 mL and exchange into Gel filtration buffer.

## Thrombin cleavage and size exclusion.

Samples are concentrated to approximately 8 mL and dialyzed into gel filtration buffer (GFB) and the tag is cleaved using a thrombin cleavage kit available from Sigma Aldrich following their standard protocol except for the buffer conditions. Complete tag cleavage is confirmed via SDS-PAGE, after which the sample is concentrated and if cysteines are present dithiothreitol (DTT) is added as a reducing agent to prevent dimerization. The sample is concentrated to $3-5 \mathrm{~mL}$ depending on the stability and quantity of the protein produced, and is fractionated once again using a FPLC through a size exclusion column (SEC) which separates proteins by size. Multiple runs are usually needed to process the sample as increased injection sizes decrease resolution, 1.2-2mL injections work best. Again fractions are assayed for prevalence of the desired protein, pooled, and concentrated to about 4-5 mL for exchange into the final NMR buffer a lower salt PBS buffer ( 50 mM sodium phosphate, 50 mM sodium chloride, 1 mM EDTA, $0.02 \% \mathrm{NaN}$ and, with a pH of 6.8 ) again DTT is added only if cysteines are present. SDS-PAGE gel examples of the purification results shown in Figure 47.

1L Gel Filtration Buffer

- To $\sim 800 \mathrm{~mL}$ of H 2 O add...
- 50 mM Sodium Phosphate Monobasic (NaH2PO4)
5.999 g
- 300 mM Sodium Chloride( NaCl )
17.532 g
- 1mM EDTA 0.37224 g for $\mathrm{Na} 2-$

EDTA-2H2O

- 0.02\% Sodium Azide (NaN3)

1 mL of $20 \% \mathrm{NaN} 3$

- pH to 7.00 and QS

Figure 47 - SDS-PAGE gels of Rabbit purification using a 25 mL Quiagen fast flow NiNATA nickel column, Sigma Aldrich thrombin cleavage kit, and 120 mL GE S75 size exclusion column

## Cleavage step

1. We use the Sigma Aldrich Thrombin cleavage kit with the thrombin bound to agarose beads
2. Take pre and post cleavage samples and run on a gel to monitor cleavage (be aware that the K24N and all P to A mutants do not shift correctly, there is a protein smear that clears up upon SEC and then looks normal in NMR analysis also the all P to A mutant will look like it shifted up upon cleavage)
3. Wash the beads in $10 x$ bed volume of GFB three times then add the protein (I usually keep the cleavage in smaller 15 mL falcon tubes to ensure correct agitation, insufficient agitation seems to lead to precipitation of the protein, if you are doing a 4 L reaction I suggest using 2 falcon tubes and 20 mL of sample)
4. Incubate at room temperature with rocking

## Table 5 - Cleavage

| Sample | Time (hours) |
| :--- | :--- |
| WT Human | 2 |
| P27A Human | 2 |
| K24N Human | 1 |
| P12,13A Human | 2 |
| All P to A Human | 4 |
| Dog | 4 |
| Mouse | 4 |
| Cow | 4 |
| Rabbit | 4 |
| Guinea Pig | 4 |

5. Recover protein using supplied filtration column and regenerate resin as described in the kit's directions
6. Add another aliquot of protease inhibitors to sample
7. Concentrate sample to $\sim 4 \mathrm{~mL}$ for Size exclusion column

Run Size exclusion column using Gel Filtration Buffer with injection volumes of about 2 mL and a flow rate of 1 mL per min on a GE HiLoad XK16/60 Superdex 75 pg column with 120 mL bed volume.

## Table 6 -SEC program guideline

| Step | Equilibrate | Inject | Elute | Requilibrate | Inject | Elute |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| Volume | 1.25 CV | 2 mL | 1.5 CV | 0.25 CV | 2 mL | 1.5 CV |

8. Run fractions corresponding to a peak on a gel and pool fractions containing the sample
9. Concentrate to $\sim 5 \mathrm{~mL}$ and Exchange into NMR Buffer

1L NMR Buffer

- To $\sim 800 \mathrm{~mL}$ of H 2 O add...
- 50 mM Sodium Phosphate Monobasic (NaH2PO4)
5.999 g
- 50 mM Sodium Chloride $(\mathrm{NaCl})$
2.922g
- 1 mM EDTA
0.37224 g for $\mathrm{Na} 2-$

EDTA-2H2O

- 0.02\% Sodium Azide (NaN3)
- pH to 6.80 and QS

10. Finally concentrate to desired NMR concentration or Freeze with $50 \%$ glycerol in $-80^{\circ} \mathrm{C}$

## Concentration determination.

Sample concentration was the extinction coefficients as calculated by the protparam program available on www.expasy.org (294). UV measurements were taken using a ND-1000 nanodrop from Thermo Fischer.

Table 7 Protein Molecular Weights and Extinction Coefficients

| Protein Molecular Weights and Extinction Coefficients |  |  |  |  |
| :--- | :--- | :--- | :--- | :--- |
| Protein | No. Amino Acids | MW- Precleave | MW-Post Cleaved (Kda) | EC (M/cm) |
| Human | 77 | 10.44 | 8.56 | 11000 |
| Guinea pig | 92 | 11.49 | 9.61 | 11000 |
| Rabbit | 91 | 11.45 | 9.57 | 11000 |
| Mouse | 84 | 11.45 | 9.57 | 5500 |
| Cow | 86 | 11.1 | 9.21 | 12490 |
| Dog | 81 | 10.62 | 8.76 | 11000 |

Sample concentrations were kept as close to 0.3 mM as practical, and with the exception of the residual dipolar coupling (RDC) all experiments were
measured in $90 \% \mathrm{H} 2 \mathrm{O} / 10 \% \mathrm{D} 2 \mathrm{O}$ in 50 mM Sodium Phosphate buffer with 50 mM Sodium Chloride 1mM EDTA and 0.02\% Sodium Azide at pH 6.8 and 4mM DTT for sequences containing cysteines. The RDC experiments were instead conducted using a pH of $6.082 \% \mathrm{H} 2 \mathrm{O} / 3 \% \mathrm{C} 6 \mathrm{E} 12 / 15 \% \mathrm{D} 2 \mathrm{O}$

## ITC data collection and analysis

ITC experiments were conducted using a GE Microcal VP-ITC. Samples were exchanged into a buffer containing 50 mM Sodium Phosphate, 150 mM sodium chloride, 1 mM EDTA, $0.02 \%$ sodium azide, 8 mM beta-mercapto-ethanol at a pH of 6.8. Solutions of wt and the mutant forms of p53TAD at a concentration of $50 \mu \mathrm{M}$ were loaded into the syringe and injected into the sample cell containing either MDM2 or MDMX at a concentration of $5 \mu \mathrm{M}$. 2810 ul injections of wt and the mutant forms of p53TAD were used for the MDMX titrations and 387.5 ul injections were used for the MDM2 titrations. The sample cell was equilibrated at $25^{\circ} \mathrm{C}$. All of the data was analyzed using the Origin70 ITC Software. The values listed in Table 1 are the averages and standard deviations from three different ITC experiments performed on the same protein preparations. The integrated ITC data was best fit with a single-site binding model and the binding stoichiometries were between 0.8 and 1.0.

The $K_{d}$ value for wt p53TAD binding to Mdm2 is consistent with previously reported $K_{d}$ values for p53TAD fragments of similar length determined using either ITC or fluorescence anisotropy (250-252). The binding affinity values measured for the proline mutants are also consistent with a recent alanine
scanning study, where a short peptide with the corresponding P27A substitution stabilized the binding to Mdm 2 by $1.26 \mathrm{kcal} / \mathrm{mol}$ (253). In another study, the proline at position 27 was mutated to serine (254). This mutant stabilized the binding to Mdm2 by $2.3 \mathrm{kcal} / \mathrm{mol}$ as determined by fluorescence polarization.

## Site directed mutagenesis

You will need:

Forward and Reverse Primers incorporating mutation

Stratagene QuikChange kit

Unmutated plasmid

NZY+ Broth

## Setting up PCR reactions.

Thaw reagents on Ice

Prepare control reaction by adding:

- $2.5 \mu$ l of $10 \times$ reaction buffer

- $0.625 \mu \mathrm{l}(125 \mathrm{ng})$ of oligonucleotide control primer \#1 [34-mer (100 $n g / \mu \mathrm{I})$ ]
- $0.625 \mu \mathrm{l}(125 \mathrm{ng})$ of oligonucleotide control primer \#2 [34-mer (100 $n g / \mu \mathrm{I})$ ]
- $0.500 \mu \mathrm{l}$ of dNTP mix
- $18.75 \mu \mathrm{l}$ of double-distilled water $(\mathrm{ddH} 2 \mathrm{O})$ to a final volume of $25 \mu \mathrm{l}$

Prepare sample Reactions, do a range of concentrations of Template Plasmid (eg 2.5, 5, 10, 25ng)

To each tube add:

- $2.5 \mu$ l of $10 \times$ reaction buffer
- $\quad \mathrm{x} \mu \mathrm{l}$ @ $\qquad$ ng/uL of respective plasmid to respective tube
- $0.500 \mu \mathrm{l}(125 \mathrm{ng} / \mathrm{ul})$ of forward mutant primer
- $0.500 \mu \mathrm{l}(125 \mathrm{ng} / \mathrm{ul})$ of reverse mutant primer
- $0.500 \mu \mathrm{l}$ of dNTP mix
- Bring to $25 \mu \mathrm{l}$ with ddH 2 O

Add $0.5 \mu \mathrm{l}$ of PfuTurbo DNA polymerase (2.5 U/ $\mu \mathrm{l}$ ) to Sample reactions and Control

## Thermal cycling.

Set up thermal cycler program using tables

Table 8 - Thermocycler program for site directed mutagenesis.

| Segment | Cycles | Temp $^{\circ} \mathrm{C}$ | Time |
| :---: | :---: | :---: | :---: |
| 1 | 1 | 95 | 30 sec |
| 2 | 30 | 95 | 30 sec |

|  |  | 55 |
| :---: | :---: | :---: |
|  |  |  |

Store on ice or in fridge till part III

## Dpn I Digestion.

The Dpn I enzyme recognizes the methylated DNA of the template plasmids and cleaves it in many places thus leaving only the mutated products of the PCR reaction.
$\square$ Add 0.500 ul of Dpn I enzyme (10 U/ul)
$\square \quad$ Blip spin microfuge tubes
$\square$ Incubate at $37^{\circ} \mathrm{C}$ for 2 hours with agitation

## Transformation.

The plasmids are transformed into the "supercompetent" XL-1 blue cells that have been selected for increased competency, and are also lacking in certain recombinase enzymes to prevent the accumulation of plasmid mutations.

This allows for the long term storage of the transformed cells in frozen glycerol stocks.
$\square$ Add 25ul of supplied supercompetent XL-1 blue cells to a sterile labeled microfuge tube

Add 0.500 ul of Dpn I digested sample to respective tubes and gently flick/tap to $\operatorname{mix}$

- There is also an optional pUC18 transformation control

Incubate on ice for 30 min
$\square$ Heat shock at $42^{\circ} \mathrm{C}$ for 30 sec

Incubate on ice for 2 min

Add 125ul of NZY+ Broth preheated to $42^{\circ} \mathrm{C}$

Incubate 1 hour at $37^{\circ} \mathrm{C}$ with shaking at 225-250 rpm

Plate whole mutagenesis control on LB-AMP plates with 80ug/ml X-gal and 20 mM IPTG

Plate 5 ul of Transformation control cells (may add 200ul of broth to plate to help spread)

Plate entire volume of samples on LB-(appropriate resistance plates)

Incubate overnight (>16hours) at $37{ }^{\circ} \mathrm{C}$

There should be 50-800 mutant control colonies with $80 \%$ being blue There should be $>250$ colonies of the transformation control with $>98 \%$ being blue

There should be 10-1000 sample colonies

## Minipreps

You will need:

Fresh transformants

Enough buffer and columns in kit for the number of reactions

Sterile microcentrifuge tubes for plasmid product

## Overnight cultures.

$\square$ Label sterile test tubes and
$\square$ Pick selected colonies and inoculate 5 ml of LB Broth + Antibiotic (50mg/L Kanamycin)
$\square$ Incubate in shaker at $37^{\circ} \mathrm{C}$ over night

## Pelleting and lysis.

$\square$ Label a set of 15 ml Falcon tubes

Pipette the full 5 ml of bacterial culture into each tube
$\square$ Close caps and centrifuge for 30 seconds at, 6000 rcf
$\square$ Save the Pellet

Add $250 \mu$ l of Buffer P1 (in fridge), vortex until pellet is resuspended

Add $250 \mu \mathrm{l}$ of Buffer P2, gently invert tube 4-6 times. Do incubate longer than 5 min (shorter is better)

Add $350 \mu \mathrm{l}$ of Buffer N3, immediately invert tube 4-6 times (be gentle!)

Centrifuge for 10 minutes at 17,900 rcf

## DNA purification by spin column.

$\square$ Pipet supernatant onto the corresponding spin column (avoid white precipitate)
$\square$ Centrifuge spin columns with collection tubes @17,900rcf for 1 min
$\square$ Empty collection tubes

Add $500 \mu \mathrm{l}$ of Buffer PB to the column

Centrifuge spin columns with collection tubes @17,900rcf for 1 min

Empty collection tubes

Add $750 \mu \mathrm{l}$ of Buffer PE to the column

Centrifuge for 1 minute at 17,900 rcf
$\square$ Place spin column in a clean (labeled) 1.5 ml microfuge tube

Add $50 \mu \mathrm{l}$ of warm sterile water or Buffer EB to the column

Let the column stand for 1-2 minutes

Centrifuge for 2 minutes at 17,900 rcf

## DNA purity and sequencing.

The plasmid DNA should be measured on the nanodrop to determine concentration, and estimate the DNA purity. The purity can be estimated by the ratios of absorbance at various wavelengths i.e. $260 \mathrm{~nm} / 230 \mathrm{~nm}$, estimates the organic solvent contamination, a ratio of greater than 2.0 is desirable, and the $260 \mathrm{~nm} / 280 \mathrm{~nm}$ ratio estimates protein contamination, a ratio greater than 1.8 is desirable. Store plasmids in the fridge. The plasmids should also be run on a 1\% agarose gel in Tris Boric EDTA (TBE) at 100 Volts for 2 hours to visualize the plasmid integrity.

Plasmids of sufficient purity and integrity are shipped to MWG operon for sequencing to confirm that the plasmid has the correct sequence.

## Spin labeling

In this section labeling refers to the paramagnetic spin labeling not the magnetically active label. Labeling was carried out as follows. ${ }^{15} \mathrm{~N}$ proteins (with cysteines) were prepared and purified as described previously. Samples should be at a concentration between 0.225 mM and 0.25 mM in 2.5 mL of NMR buffer with 4 mM of DTT. 3 PD10 desalting columns from GE are needed for each protein labeled. The PD10 columns should be pre-equilibrated (5CV) with NMR
buffer not containing DTT. 5 mg of MTSL should be dissolved in 200uL of ethanol. Since the polypeptides have reduced cysteines by necessity, it is important to complete the desalting rapidly, and to expose the cysteines to an excess of MTSL quickly - the 5mg yields greater than tenfold excess.

When ready load the 2.5 mL of protein onto the column and discard the flow-through, then elute with 3.5 mL of NMR buffer no DTT bring to 5 mL , and split into two 2.5 mL samples and immediately load 2.5 mL onto each of the other PD10 columns, discarding flow-through and eluting with 3.5 mL each. Again immediately add the MTSL/ethanol to eluate. Incubate with MTSL at $37^{\circ} \mathrm{C}$ for 2 hours. While waiting re-equilibrate the PD-10 columns with NMR buffer no DTT (5CV). The labeled protein should be brought to 7.5 mL and split in three and loaded on the re-equilibrated PD-10 columns to remove any excess MTSL, and are eluted with 3.5 mL each using NMR buffer no DTT, this is important to prevent excessive signal broadening by MTSL not covalently bound to the protein. You should now have 10.5 mL of paramagnetically labeled protein at a concentration of approximately 0.06 mM , concentrate to a usable concentration for NMR determination (0.3-0.35mM).

Concentrate the remaining sample down to $100 \mu \mathrm{~L}$ and exchange into nanopure water by repeated dilution and concentration using the centrifugal concentrator units, a similar control should be carried out on a sampling of unlabeled protein. These samples are then analyzed by mass spectrometry to determine the molecular weight of the polypeptide to confirm labeling efficiency. The MTSL Moeity should add 186.3 Daltons to the MW of the protein. Do not
forget to account for ${ }^{15} \mathrm{~N}$. The ratio of the labeled peak intensity to that of the unlabeled peak intensity gives the labeling efficiency, it should be greater than 90\%.

In total each PRE experiment should collect three HSQC spectra, the unlabeled, labeled oxidized, and labeled reduced. The unlabeled spectra is a control to verify any excessive peak shifts from the cysteine mutant. The labeled and oxidized sample gives the spectra with the broadened peaks as a function of proximity to the label, and finally the labeled and reduced sample rescues the peak intensities by quenching the unpaired electron. This is accomplished by adding an excess of Ascorbic acid. This is done by adding a tenfold excess with fresh 1 M ascorbic acid $\sim 1.8-2.1 \mu \mathrm{~L}$. This concentration was confirmed to not excessively shift the pH of the buffered sample.

## Partial alignment media

Several sample conditions were tried for RDC measurement. The final conditions used were as follows. 50 mM sodium phosphate, 50 mM sodium chloride, 1 mM EDTA, $0.02 \%$ sodium azide $15 \%$ D20, and 4 mM DTT if cysteines are present at pH 6.0 . The first step is to collect the isotropic control IPAP experiments. Process the In phase, and Out of phase FIDs as normal, the two *.ft2 files are then combine using the IPAP_math.prl script which generates two new spectra, one that is the addition of the two spectra while the other subtracts the one signal from the other, this results in each spectra "add" and "sub" that each only has one of the two coupled peaks. The distance between these peaks
becomes the isotropic peak splitting control $(\sim 94 \mathrm{~Hz})$ from which the anisotropic split is subtracted.

The partial alignment was forced using conditions as follows, 3\% hexaethylene glycol monododecyl ether (C6E12), with a hexanol molecular ratio of 0.64 . This works out to $18 u \mathrm{~L}$ of C6E12, 90 uL of D20 (buffered) 492uL of protein, and $\sim 3.4 \mathrm{uL}$ of n -Hexanol. The C6E12 is highly viscous so care should be taken when pipetting, it was useful to mix the C6E12 and D20 before the addition of the protein. The n-hexanol is then pipetted one uL at a time with vigorous vortexing between, it will be opaque but when the liquid crystal matrix has formed the solution should return to translucency. It is important to maintain the temperature within the acceptable range of the matrix or the lamellar phase will collapse, in the case of C6E12 this is essentially between 23 and $30^{\circ} \mathrm{C}$. I found that is was sufficient to hold the tube in my hand but wrapped in a kimwipe. The same two IPAP experiments are carried out, but the locking must be done manually and the peak splitting between the D2O peaks must be measured over a time range to assure that a stable matrix has been formed. The fids are processed as before and the difference in peak splitting is measured.

## Appendix E-BEGR Figures

Figure 49 - Fitting the Broad Ensemble without noise. Correlation plots with the BEGR CA $\Delta \delta$ on the $Y$ axis as a function of the NMR experimental values. Green circles represent the $\Delta \delta$ of the unweighted ensemble CAs, the blue represents the weighted ensemble CA $\Delta \delta$ using $100 \%$ noise. The red line is added as a reference for a perfect correlation. These four fits are for one replica each, and are representative of the other two.

Figure 50 - RMSD plots of the ensembles vs the Mdm2 bound structures without noise. Each panel displays the frequency of a structure within the ensembles with the RMSD on the $x$ axis. The top left panel shows the three wt human, bottom left corresponds to the P27A mutant, the top right is the guinea pig, and the bottom right is for dog. Each panel shows all three ensembles in red, green and blue.

Figure 51 - RMSD plots of the ensembles vs the RPA70 bound structures without noise. Each panel displays the frequency of a structure within the ensembles with the RMSD on the $x$ axis. The top left panel shows the three wt human, bottom left corresponds to the P27A mutant, the top right is the guinea pig, and the bottom right is for dog. Each panel shows all three ensembles in red, green and blue.

Figure 52 - Fractional Helicity of Reweighted Ensembles without noise. Each panel represents three separate one million pool ensembles reweighted using the CA $\Delta \delta$ with $100 \%$ noise. The plots show the resulting average fractional of the weighted ensemble for each residue. The top left panel is for wt human, bottom left is for the single proline mutant P27A, top right is guinea pig, and bottom right is the dog.
