#### Abstract

The Slave River Delta (SRD), NWT, represents a pivotal node in the upper Mackenzie Basin watershed and is a productive northern wetland landscape with a rich natural and cultural heritage. Concerns over environmental consequences of natural and anthropogenic-driven decline in river discharge as well as climate variability have prompted hydroecological studies to improve understanding of how this ecosystem functions over time and space. However, long-term natural hydrological variability of the Slave River system is not well documented and needs to be further developed. In order to provide a temporal context for understanding and evaluating the impacts of climate variability and change and other stressors on Slave River discharge, multi-proxy paleolimnological analyses have been conducted to reconstruct a long-term record of hydrologic variability in the Slave River system. Study sites include two small closeddrainage lakes (GSL1, SD34) located near a former elevated strandline of Great Slave Lake and another lake (SR1) located upstream on an island in the Slave River.

Multi-proxy analysis of lake sediment cores collected from SD34, GSL1 and SR1 provided a $\sim 1200$-year record of water level variation for the Slave River and Great Slave Lake. Sediment composition and elemental and stable isotope geochemistry proved to be sensitive indicators of hydrologic change within the study basins. Interpretation of $\mathrm{C} / \mathrm{N}$ ratios and $\delta^{13} \mathrm{C}_{\text {org }}$ values from SD34, GSL1 and SR1 additionally indicated that conventional, straightforward interpretation of these commonly applied paleolimnological measurements is not always appropriate.

Prior to the onset of the last millennium, during the Early Medieval period (MP), high $\mathrm{C} / \mathrm{N}$ ratios, low $\delta^{18} \mathrm{O}_{1 \mathrm{w}}$, high $\delta^{13} \mathrm{C}_{\mathrm{org}}$ and inorganic sediment indicated open-drainage

conditions caused by riverine inundation of both study lakes. River inundation of SD34 and GSL1 was attributed to Slave River discharge dominated by a large flashy spring freshet and high ice-jam flood frequency.

The percent organic carbon, organic nitrogen, $\delta^{15} \mathrm{~N}, \mathrm{C} / \mathrm{N}$ ratios, $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values and $\delta^{13} \mathrm{C}_{\text {org }}$ values appear to indicate isolation of SD34 and GSL1 from the Slave River at $\sim 1000 \mathrm{AD}$ and $\sim 1150 \mathrm{AD}$, respectively. However, reduced ice-jam flood frequency in the SRD precedes a similar change in the upstream Peace-Athabasca Delta (PAD) by $\sim 400$ years. A change in the distributary network of the SRD and low Slave River discharge may account for the $\sim 400$ year offset and explain why SD34 and GSL1 became isolated from ice-jam flooding during the Middle MP, when ice-jam flood frequency was high in the PAD.

The interval of low Slave River discharge suggested by SD34 and GSL1 sediment records appeared to end at $\sim 1300 \mathrm{AD}$ with the re-emergence of open-drainage conditions in SD34 indicated by high $\delta^{13} \mathrm{C}_{\text {org }}$ values. Open-drainage conditions at SD34 spanned the Late MP and were attributed to high Slave River discharge that is consistent with an interval of high North Saskatchewan River discharge.

The SR1 C/N record indicated that high Late MP Slave River discharge continued throughout the Little Ice Age (LIA). High LIA Slave River discharge was attributed to a delay in snowmelt-generated runoff that sustained higher summer river discharge as a result of a shift to cooler climate conditions. High $\delta^{13} \mathrm{C}_{\text {org }}$ values in the GSL1 record indicated open-drainage conditions in GSL1 throughout the LIA and $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ values that were similar to modern Great Slave Lake (GSL) $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values suggested that the opendrainage conditions were the result of GSL inundation. Therefore, increased Slave River
discharge appears to have caused high GSL water levels during the LIA, sımilar to that observed upstream in Lake Athabasca. High GSL water levels inundated GSL1 and likely occupied the strandline visible in the landscape to the south of the SRD.

At the beginning of the $20^{\text {th }}$ century, the SR1, SD34 and GSL1 sediment records indicate closed-drainage conditions were established. Closed-drainage conditions at each study lake were attributed to a decline in water level within the Slave River system at the end of the LIA A $20^{\text {th }}$ century decline in discharge parallels a shift to a warmer climate regime that has been shown to cause an earlier, more rapid melt of the spring snowpack in the headwaters of the Peace and Athabasca rivers. The sediment records of the three study lakes indicated that water levels within the Slave River system have declined from the high levels that characterized the LIA, falling to levels possibly similar to the MP. However, high $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values at GSL1, throughout the $20^{\text {th }}$ century that are unique within the $\sim 1200$ record may suggest that present hydrological conditions at this site are unprecedented in the last $\sim 1200$ years.

These findings establish a link between hydrologic conditions within the Slave River system and those upstream in the PAD and Lake Athabasca. Sediment records from SD34, GSL1 and SR1 demonstrated that in the past $\sim 400$ years, the hydrology of the Slave River system responded similarly to the PAD in response to shifting climate regimes. This indicates that hydrologic change upstream in the headwaters of the Slave River has historically translated downstream to the SRD and GSL. Furthermore, these results show that water levels in the upper Mackenzie River system have varied considerably in the last $\sim 1200$ years and that they have been in dechne over the last 200 years - a decline that is likely to continue given expected trajectories in river discharge.

## Acknowledgements

I would like to thank my advisor Dr. Brent Wolfe for his time, patience, support and guidance which have been given from start to finish. Your passion for this work is contagious and has made the writing process much easier. I would also like to thank Brent for allowing me the opportunity to participate in field work outside the scope of my own project I would lıke to sincerely thank my co-advisor Dr. John Johnston for his time, patience and enthusiasm. Thank you for helping me think outside the box and for bringing a different perspective to the table that was always appreciated.

I am thankful to the following people for providing me with help and support during lab work and all other components of the thesis process: Dr. Brent Wolfe, Dr. John Johnston, Dr.Thomas Edwards, Dr. Roland Hall, Johan Wiklund, Bill Mark, Bronwyn Brock, Michelle Tai, Paige Harms, Caleb Light, Stephanie Lyons, Erin Dobson, Kevin Turner, Nick Sidhu and the rest of the MBD/NHL group. I would like to thank the following organizations for providing funding for fieldwork and analytical support:

NSERC Northern Research Chair Program, Northern Scientific Training Program and the Polar Continental Shelf Program.

I would like to thank my family for all their support and encouragement. A special thank you to Suzanne Hatch for being there for me throughout the whole Masters process with continued support and encouragement. As well, an additional thank you to Caleb Light, Eric Thuss, Erin Dobson, Eric Sadowski and Andrea Kenward for "Wednesday Lunch Beers".

## Chapter 1- Introduction

### 1.1 Introduction

The Slave River Delta (SRD) (Figure 1) is located on the southeast shore of Great Slave Lake (GSL) at the terminus of the Slave River. The SRD is a productive northern wetland landscape, home to a variety of unique plant and animal assemblages (Milburn et al., 1999). Deltaic landscapes such as the SRD are ecologically significant because they are more productive than other components of northern river systems (Milburn et al., 1999). The SRD is also of great cultural importance to the Deninu Ku'e First Nation community of Fort Resolution who utilize natural resources in the delta to support and maintain traditional lifestyles (Wolfe et al., 2007a).

The Slave River is part of the upper Mackenzie River system and is sourced predominantly by the Peace and Athabasca rivers. There are several potential stressors on the Peace-Athabasca-Slave river system. The Peace River was regulated in 1968 by the construction of the WAC Bennett Dam at Hudson's Hope, British Columbia.

Additionally, growing energy demand has led to increased interest in hydroelectric development on the Slave River near Fort Smith (Hannaford, 2008). Increasing water withdrawal from the Athabasca River for oil sands production has recently put additional stress on the river system (Campbell and Spitzer, 2007). As well, climate change in recent years has caused the recession of alpine glaciers and a decline of snowpacks (Schindler and Donahue, 2006). This has resulted in a reduction in source water entering alpine-sourced rivers systems such as the Peace-Athabasca-Slave river system. All of these factors potentially influence the flow of water in the Slave River, but how these changes in river discharge may affect the SRD is not fully understood.

Figure 1 Slave River Delta and study lakes SR1, SD34 and GSL1 A former strandline of GSL visible in the landscape durmg the 2007 field season is also highlighted

The ability to predict future evolution of northern rivers is difficult because of a lack of long-term river and climate data for Canada's North (Rouse et al., 1997; Schindler and Donahue, 2006). The paucity of river gauging stations and short duration of available records provide limited insight into natural variability in discharge of northern river systems. Studies by Dery and Wood (2005) and Dery et al. (2009) have shown that hydrologic trends inferred from short-term records are susceptible to drastic change (reversal of trend) in response to fluctuating discharge over short periods of time. Longer hydrologic records than those available are then required to strengthen understanding of natural variability within northern river systems such as the Slave River. Long-term records of hydrologic variability within northern river systems would provide the knowledge required to make informed water resource management decisions (Sear and Arnell, 2006).

Extensive studies in the Peace-Athabasca Delta (PAD), upstream from the SRD by Wolfe et al. (2005, 2006, 2008a,b) have demonstrated the effectiveness of using multiproxy paleolimnological reconstruction as a tool for developing long-term hydrologic records to supplement sparse discharge data for a northern river system. Wolfe et al. $(2005,2006,2008 \mathrm{a}, \mathrm{b})$ analyzed sediment cores from several PAD lakes in response to reports of less frequent and extensive spring flooding, declining lake levels and loss of wildlife habitat since the regulation of the Peace River (at the WAC Bennett Dam). These studies aimed to distinguish the effects of multiple stressors on the hydrological regime of a northern river system and to provide temporal context for the evaluation of causes affecting contemporary hydrological change. Results have indicated that the drying of PAD lakes can occur at a variety of time scales in the absence of spring river flooding.

Some lakes may last decades without the input of river water and others may dry up within years (Wolfe at al., 2005; Peters et al., 2006). Wolfe et al. $(2006,2008 a)$ also indicate that river flooding over the last several centuries has oscillated between multidecadal intervals of both high and low flood frequency, suggesting significant natural variability in spring river flood frequency. As well, the most recent interval of low flood frequency in the PAD began several decades before the construction of the WAC Bennett Dam (Wolfe et al., 2006). Wolfe et al. (2008a,b) suggesting that changes in headwater climate and local geomorphic changes in Athabasca River flow appear to be the dominant drivers of river discharge and flooding in the PAD.

Using reconstructions of winter temperature and growth season relative humidity in the Columbia Icefield based on isotope analysis of tree-ring records, Edwards et al. (2008) described past climate of the eastern Rocky Mountains in the headwaters of the Athabasca River. During the past millennium, the upper Mackenzie River system has been characterized by a three-phase climate history, which includes the Medieval Period (MP) (AD $\sim 1000$ to $\sim 1530$ ), Little Ice Age (LIA) (AD $\sim 1530$ to $\sim 1890$ ) and $20^{\text {th }}$ century. The climate of the MP consisted of relatively warm winters and higher relative humidity during the growth season and the LIA was characterized by a transition to colder temperatures and low growth season relative humidity (Edwards et al., 2008). Since the end of the LIA, temperature and relative humidity have increased and the climate reconstruction suggests that conditions may be returning to those similar to the early millennium.

Wolfe et al. (2008a), Sinnatamby et al. (2010) and Johnston et al. (2010) have demonstrated significant variability in discharge within the Peace-Athabasca river system
over the last 1000 years in response to the changing climate patterns in the eastern Rocky Mountains outlined by Edwards et al. (2008). For instance, water levels in Lake Athabasca increased from a low at the onset of the millennium (MP) to a high during the LIA (Wolfe et al., 2008a; Sinnatamby et al., 2010; Johnston et al., 2010). Lake level variation over this period has been influenced by changes in summer discharge through the Peace-Athabasca river system. During the MP, warmer temperatures caused an earlier spring melt in headwater regions and a "flashy" spring freshet, which resulted in frequent, high-magnitude ice-jam flood events but low summer discharge and low Lake Athabasca water levels (Figure 2). During the LIA, colder temperatures delayed the spring melt in the Peace-Athabasca headwater regions, resulting in sustained high summer discharge that raised Lake Athabasca water levels $\sim 2.3 \mathrm{~m}$ above contemporary levels (Wolfe et al., 2008a; Sinnatamby et al., 2010; Johnston et al., 2010) (Figure 2).

Figure 2. Reconstructed and projected hydrographs for rivers draining the hydrographic apex of North America (Wolfe et al., 2008a).

Since the end of the LIA ( $\sim 1900 \mathrm{AD}$ ), river discharge in the Peace-Athabasca river system has been in decline causing Lake Athabasca water levels to decrease (Wolfe et al., 2008a). If current trends of decreasing discharge persist, summer discharge in the PeaceAthabasca river system may fall below the low levels reconstructed for the $11^{\text {th }}$ century (Figure 2). Lake Athabasca and GSL are both natural reservoirs in the same river system and their water levels have been shown to respond comparably during wet and dry years (Bennett, 1970). As a result, it is likely that in the past millennium GSL has experienced periods of high and low water level similar to those documented by Wolfe et al. (2008a), Sinnatamby et al. (2010), and Johnston et al. (2010) for Lake Athabasca. Evidence of fluctuating Great Slave Lake water levels similar to Lake Athabasca would provide new insight into the natural forcing factors that contribute to variability in Slave River discharge.

While there has been extensive study upstream in the PAD and Lake Athabasca, a long-term record of Slave River hydrologic variability is lacking. Using multi-proxy paleolimnological methods, Brock et al. (2010) were able to supplement the 47 -year gauged record of the Slave River by generating an 80-year record of flood frequency for an SRD lake. The 80-year record indicates flood frequency was lowest prior to upstream river regulation and that the onset of river regulation coincided with a period of increased flood frequency. Changes in flood frequency at the SRD, as determined by Brock et al. (2010), paralleled those observed in the flood frequency records developed by Wolfe et al. (2006) for the PAD, suggesting climate is the dominant driver of change in runoff regime for both the SRD and PAD. However, the Brock et al. (2010) record is still relatively short and does not address long-term hydrologic variability in the Slave River
system. A long-term record of hydrologic variability of the SRD would not only provide new insight to the relationship between the PAD and SRD (two large important wetland systems in the upper Mackenzie River Basin), but more importantly, would provide understanding of the Slave River system's response to a variable climate. Such knowledge is critical in establishing a historical context of natural hydrologic variability within the Slave River system A context of natural variability coupled with an understanding of the relationship between climate and river discharge is critical for making informed management decisions. The importance of informed management of the Slave River system may be amplified in the near future as discharge through the system is expected to decline as a result of declining glacier melt contributions and snow pack runoff in headwater regions (Barnett et al., 2005, Lapp et al., 2005, Rood et al., 2005).

### 1.2 Objectives

The objective of this study is to establish a long-term hydrologic record for the Slave River and gain a better understanding of the relationship between climate variation over the past 1200 years and Slave River hydrology. Such a record would extend beyond the instrumental records (47 years) of the Slave River and the flood frequency record established by Brock et al. (2010) ( $\sim 80$ years). Research questions that multi-proxy geochemical analyses will address include: 1) How has Slave River discharge changed over the past millennium and what is its relationship to climate? 2) How does variation in Slave River discharge compare to paleohydrological records of the upstream PAD? and 3) Does the postulated strandline south of the SRD observed during field study in March 2007 (Figure 3) correspond to a GSL hıgh-stand during the LIA similar to the high-stand of Lake Athabasca documented by Sinnatamby et al. (2010) and Johnston et al. (2010)? Information gained here regarding the relationships between climate and discharge as well as the Slave River and PAD can be used to inform water resource management within the upper Mackenzie River basin.

Figure 3. Possible strandline of Great Slave Lake is shown by dashed line. The relict river channel GSLl terminating at the potential shoreline is also indicated (photo taken March 2007, facing north).

## Chapter 2 -Study Site

### 2.1 Slave River-Great Slave Lake System

The Slave River flows through relict deltaic and alluvial sediments, deposited after the retreat of the Keewatin Ice Sheet. The Slave River and GSL are located within former Glacial Lake McConnell. Outflow and glacial isostatic adjustment resulted in Lake McConnell draining by 8300 BP (Vanderburgh and Smith, 1988) leaving present-day Lake Athabasca, GSL and Great Bear Lake as remnants of the second largest glacial lake in North America. Observations of the landscape surrounding GSL have indicated that lake water levels have declined more then 90 m from early post-glacial conditions (Rawson, 1950). Since the draining of Glacial Lake McConnell, sediment carried by the Slave River has been deposited in the southern arm of GSL forming the SRD. Since 1180 ${ }^{14} \mathrm{C}$ yr BP, progradation of the delta has occurred at an average rate of 10 m per year, and the relict delta now covers an area of $\sim 8300 \mathrm{~km}^{2}$ (Vanderburgh and Smith., 1988). Currently, only about $5 \%$ of the SRD is actively prograding and at a much slower rate than the historical average (Vanderburgh and Smith, 1988).

The Slave River flows for 420 km north from its origin at the confluence of the Peace River and Rivière des Rochers in the Peace-Athabasca Delta (PAD). The channel remains relatively straight for the majority of its length, but as it nears the SRD, meander bends and island bar complexes become more prevalent (Figure 1). The Peace River contributes $\sim 66 \%$ of the flow to the Slave River (English et al., 1997) with the bulk of remaining water input supplied by the Athabasca River and Lake Athabasca. The Slave

River terminates at the SRD, and accounts for the majority of annual water input to GSL, a primary source of water for the Mackenzie River.

The Peace-Athabasca-Slave system drains approximately $615,000 \mathrm{~km}^{2}$ and discharges at an annual rate of $\sim 3,400 \mathrm{~m}^{3} / \mathrm{s}$ into GSL (Prowse et al., 2002), accounting for $\sim 75 \%$ of total inflow to the lake (Gibson et al., 2006a). GSL occupies $\sim 27,200 \mathrm{~km}^{2}$ with a maximum length of 440 km and width of 160 km and has a total volume of $\sim 1.58 \times 10^{12} \mathrm{~m}^{3}$ (Rawson, 1950). The mean water level of GSL (from 1939-99) is approximately $166.60 \pm 0.22$ masl. However, there is considerable variability in lake level, both annually and interannually, with an historical annual range of $\sim 1.2 \mathrm{~m}$ (Gibson, 2006b). The water balance of GSL is dominated by river flow, accounting for $95 \%$ of the input and $93 \%$ of the output. As a result, the water level of GSL is subject to both seasonal and annual fluctuations driven predominantly by variation in Slave River discharge (Rawson, 1950). Maximum water levels occur in late May and early June corresponding to peak river flow and minimum levels occur in April when Slave River discharge is lowest (Gibson et al., 2006b). Fluctuations of inflow to the Slave River from headwater regions in the eastern Rocky Mountains have been shown to influence the instrumental (~past 50 years) water balance of GSL (Gibson et al., 2006b). High (low) water levels within GSL correspond to increased (decreased) discharge through the Peace-Athabasca-Slave system (Gibson et al., 2006a). This indicates that a longer record of GSL water level change would be useful for identifying climatic and hydrologic variability within the upper Mackenzie River system (including the SRD).

The SRD contains a variety of small lakes and wetlands, spanning a range of hydrological settings. SRD lakes were classified based on the dominant process affecting
their water balances during the 2003 thaw season (Brock et al., 2007). SRD lakes were classified as evaporation-, flood- or exchange-dominated. Evaporation-dominated lakes have water balances controlled by snowmelt in the spring followed by evaporation and precipitation during the summer months and are generally not affected by river flooding during the spring melt. The water balance of exchange-dominated lakes is variable throughout the thaw season and depends mainly on the strength of seiche events on GSL or Slave River inflow. Flood-dominated lakes have water balances that are largely controlled by river flooding during the spring break-up. Spring break-up flooding is important in a northern delta such as the SRD because it provides water to lakes otherwise isolated from the main drainage network of the Slave River (Brock et al., 2007, 2008; Sokal et al., 2008). The pulses of water from spring break-up flooding replenish water levels and introduce sediment to lake beds (Milburn et al., 1999; Rouse et al., 2007). The occurrence and magnitude of flooding in the SRD depends predominantly on the amount of Slave River discharge during the spring breakup (Brock et al., 2008). Because Slave River discharge is dependent on snow accumulation and rate of melt in its source regions, changes in upstream hydrologic conditions can have significant influence downstream in the lakes of the SRD (Brock et al., 2008).

### 2.2 Study Basins

Multi-proxy paleolimnological analyses were conducted on sediment cores retrieved from three study basins: SR1 (Figure 1, 4, 5), GSL1 (Figure 1, 6) and SD34 (Figure 1, 7) to gain insight into multi-centennial hydrologic change in the Slave River system. SR1 was chosen because it is located upstream from the SRD and was expected to provide a record of Slave River water level outside of the active delta and SD34 was chosen because it was anticipated to record high Slave River water levels within the contemporary delta. GSL1 is located outside of the active delta, adjacent to a strandline south of the SRD (Figure 3) and was chosen because it was expected to provide a record of high GSL water levels. All three basins are currently isolated from hydrological influence of the Slave River and GSL.
$221 S R 1\left(60^{\circ} 48^{\prime} 097^{\prime \prime} N, 113^{\circ} 13 \prime 339^{\prime \prime} W\right)$
SR1 is a small basin ( $\sim 100 \mathrm{~m}$ in length) that at the time of coring (March 24, 2007) was $\sim 90 \mathrm{~cm}$ deep (Figure 4,5). This basin is located on a large island ( $\sim 10 \mathrm{~km}$ long and $\sim 1.5 \mathrm{~km}$ wide) on the Slave River, $\sim 60 \mathrm{~km}$ upstream from the SRD . The island has no evidence of recent flooding and the basin is surrounded by mature spruce forest, with no evidence of inflow or outflow channels (Figure 4,5). It is expected that SR1 would only experience flooding during periods of Slave River discharge higher than the present.

Figure 4. SR1 (March 2007, facing north).

Figure 5. SR1 (March 2007, facing north).

### 2.2.2 SD34 ( $61^{\circ} 11^{\prime} 41^{\prime \prime} N, 113^{\circ} 33^{\prime} 49^{\prime \prime} W$ )

SD34 (Figure 6) is located in the relict region of the SRD, $\sim 6 \mathrm{~km}$ northeast of Fort
Resolution. The lake is kidney-shaped with a maximum length of $\sim 600 \mathrm{~m}$ and is less than
2 m at its deepest point. The lake appears to be located at an elevation of $\sim 159$ metres above sea level (masl) (Figure 7). SD34 contains no inflow or outflow channels.

Presently, the lake is isolated from the Slave River and its distributaries and is not flooded by river water during the spring break-up, even during large spring break-up floods like that of 2005 (Brock et al., 2008). SD34 was classified as an evaporationdominated basin by Brock et al. (2007).

Figure 6. SD34 (May 2005, facing east)

Figure 7. Topographic map of SRD area including GSLI and SD34 (Atlas of Canada, 2006). 160 $m$ contour lines are indicated by thick black line, spot elevations in close proximity to GSL1 and SD34 are also highlighted. Elevation of GSL1 is approximated to be between 161 masl to 163 masl based on spot elevations in the vicinity of the lake and the proximity of the lake to 160 masl contour line. Elevation of SD34 is approximated to be 159 masl based on its location between two 160 masl contour lines and its close proximity to a 159 masl spot elevation.

### 2.2.3 GSLI ( $61^{\circ} 11$ '41'' $\left.N, 113^{\circ} 33^{\prime} 49^{\prime \prime} W\right)$

GSL1 is the terminal end of a relict river channel that was likely a former distributary channel of the Slave River (Figure 8). It is located $\sim 2.5 \mathrm{~km}$ east of the current GSL shoreline and $\sim 8 \mathrm{~km}$ southeast of Fort Resolution (Figure 1). The main body of the basin is shallow ( $<2 \mathrm{~m}$ deep) and has a length of $\sim 2 \mathrm{~km}$ and width of $\sim 150 \mathrm{~m}$. The elevation of GSL1 appears to be between $\sim 161-163$ masl (Figure 7), $\sim 3.6-5.6 \mathrm{~m}$ higher in elevation than the highest gauged GSL water level (157.23 masl) (Gibson, 2006b). Currently, the lake is located outside the range of contemporary river flooding (see Brock et al., 2008). However, a possible former strandline of GSL observed near this site during field study in March 2007 suggests the area may have been flooded during a high-stand of GSL (Figure 9). The strandline is marked by a change in the spatial distribution of lakes and the termination of several relict river channels (such as GSL1) (Figure 9). A greater concentration of lakes likely indicates poorer drainage on the GSL side of the strandline.

Figure 8. GSLI (March 2007, facing northeast). Figure 9. GSL strandline (March 2007, facing south).

## Chapter 3 - Field and Laboratory Methods

### 3.1 Retrieval of Sediment Cores

Lake sediment cores were collected for each study lake (SD34, GSL1 and SR 1) through lake ice in March 2007 using gravity and Russian peat corers. Gravity cores were collected using a Glew gravity corer, driving a tube (open at both top and bottom) vertically into the lake sediment using gravity (Glew et al., 1989). The cores were then sectioned into $0.5-\mathrm{cm}$ intervals at the field station. The Russian peat coring process involved the use of a chamber corer. In the closed position, the chamber corer was driven vertically into the sediment with drive rods. While maintaining its vertical orientation, the corer was then rotated capturing the sediment within the chamber and the Russian peat corer was then removed (Glew et al., 2001). Russian cores were then sectioned into 0.5cm intervals in the laboratory at Wilfrid Laurier University. The combination of gravity and Russian cores is effective for providing a sedimentary record for the recent past because the gravity core preserves the integrity of the uppermost sediment sequence and the Russian corer can penetrate more deeply than the gravity corer, extending the sediment record.

Several cores were taken from each study lake (Table 1 and 2). Gravity cores were denoted KB and Russian cores were denoted RC. Depths and names of all cores taken are presented in Table 1. For SR1, the KB-2 core was used for analysis because it had a more defined sediment-water interface than KB-1, indicating that the uppermost sediments had been less disturbed during the core retrieval process. For SD34, the KB-2 core had a better defined sediment-water interface than KB-1 and was used for analysis. Two RC
cores were also taken from SD34. SD34 RC-2 was used for analysis because it appeared to have preserved a greater amount of the uppermost sediment than RC-1. One of each core type was taken from GSL1 and as a result KB-1 and RC-1 cores were used for analysis. Russian cores from SD34 (SD34 RC-2) and GSL1 (GSL1 RC-1) were aligned to their corresponding gravity cores (SD34 KB-2 and GSL1 KB-1) using percent organic matter values. Once aligned, the Russian core depths were adjusted to account for missing surface sediment.

Table 1 Summary of gravity cores

| Study <br> Lake | Coring Date <br> (2007) | Gravity Core Name | KB Core Depth <br> (cm) |
| :---: | :---: | :---: | :---: |
| SR1 | March 24 | SR1 KB-1 | 54.0 |
| SR1 | March 24 | SR1 KB-2 | 39.5 |
| SD34 | March 24 | SD34 KB-1 | 365 |
| SD34 | March 24 | SD34 KB-2 | 38.0 |
| GSL1 | March 25 | GSL1 KB-1 | 26.5 |

Table 2 Summary of Russian cores

| Study Lake | Russian Core <br> Name | RC Core Depth <br> (Field Measurement) <br> (cm) | RC Core Depth <br> (Adjusted in Lab) <br> (cm) |
| :---: | :---: | :---: | :---: |
| SR1 | SR1 RC-1 | $4-100$ | Not analyzed |
| SD34 | SD34 RC-1 | $7-54$ | Not analyzed |
| SD34 | SD34 RC-2 | $0-66$ | $45-75.5$ |
| GSL1 | GSL1 RC-1 | $0-95$ | $05-100$ |

### 3.2 Laboratory Methods

### 3.2.1 Loss-on-Ignition Analysis

Loss-on-ignition (LOI) is frequently used to determine moisture content, bulk organic matter content and inorganic content of lake sediment (Dean, 1974; Heiri et al, 2001). Organic content profiles are of greatest interest to this study as they can potentially reveal patterns and trends in lake productivity, organic matter diagenesis and terrestrial organic matter and inorganic matter inputs over time. Additionally, in order to establish a continuous stratigraphic record for SD34 and GSL1, LOI results were used to align the gravity and Russian cores.

LOI was conducted at $0.5-\mathrm{cm}$ intervals on samples from SR1 KB-2 $(0 \mathrm{~cm}$ to 39.5 cm ), SD34 KB-2 ( 0 cm to 38.0 cm ), SD34 RC-2 ( $4.5-\mathrm{cm}$ to $75.5-\mathrm{cm}$ ), GSL1 KB-1 ( 0 cm to 26.5 cm ) and GSL1 RC-1 ( 0.5 cm to 43.5 cm ). Wet sediment samples from each interval (approximately 0.5 grams) were weighed before and after heating at $90^{\circ} \mathrm{C}, 550^{\circ} \mathrm{C}$ and $950^{\circ} \mathrm{C}$. The weight loss during each temperature stage was measured and provides an estimate of the water content (1), organic matter content (2), mineral content (3) and carbonate content (4) of the sediment samples.
(1) Water content, $\mathrm{LOl}_{90}=\left(\left(\mathrm{WW}-\mathrm{DW}_{90} / \mathrm{WW}\right)^{*} 100\right.$
(2) Organic matter content, $\mathrm{LOI}_{550}=\left(\left(\mathrm{DW}_{90}-\mathrm{DW}_{550}\right) / \mathrm{DW}_{90}\right)^{*} 100$
(3) Mineral matter content, $\mathrm{LOI}_{950}=\left(\left(\mathrm{DW}_{90}-\mathrm{DW}_{950}\right) / \mathrm{DW}_{90}\right) * 100$
(4) Carbonate content, $\% \mathrm{CaCO}_{3}=\left(\mathrm{LOI}_{950} / 0.44\right)$
*WW wet weight of sample, before heating to $90^{\circ} \mathrm{C}$
DW dry weight of sample, after heating to $90^{\circ} \mathrm{C}$
(Heiri et al., 2001).

### 3.2.2 Sediment Chronology

A ${ }^{210} \mathrm{~Pb}$-based sediment chronology was developed for each study lake. Total ${ }^{210} \mathrm{~Pb}$ activity is a measure of both unsupported ${ }^{210} \mathrm{~Pb}$, the result of atmospheric fallout, and supported ${ }^{210} \mathrm{~Pb}$, which occurs naturally within the sediment column as the result of in situ ${ }^{226} \mathrm{Ra}$ decay (Appleby, 2001). Supported ${ }^{210} \mathrm{~Pb}$, in equilibrium with ${ }^{226} \mathrm{Ra}$, can be subtracted from the total ${ }^{210} \mathrm{~Pb}$ inventory, and the amount of unsupported ${ }^{210} \mathrm{~Pb}$ can then be determined. The unsupported ${ }^{210} \mathrm{~Pb}$ value for each sediment interval can be used to determine the sediment age using the radioactive decay of ${ }^{210} \mathrm{~Pb}$ ( 22.26 yrs ), to produce a chronology for the core over the period of time that unsupported ${ }^{210} \mathrm{~Pb}$ is present $(\sim 150$ years) (Appleby, 2001). The Constant Rate of Supply (CRS) model (Appleby, 2001) assumes a constant flux of ${ }^{210} \mathrm{~Pb}$ to the sediment, independent of changes in sedimentation rates, was used to establish the core chronologies.

The peak activity of ${ }^{137} \mathrm{Cs}$, usually reported as 1963 , can also provide a stratigraphic marker for sediment chronologies (Appleby, 2001) and was measured using gamma spectrometry. ${ }^{137} \mathrm{Cs}$ values may peak at 1963 in stratigraphic records because this was when peak fallout occurred from above ground nuclear bomb testing, which released ${ }^{137} \mathrm{Cs}$ into the atmosphere.
${ }^{210} \mathrm{~Pb}$ and ${ }^{137} \mathrm{Cs}$ analysis were conducted on SR1 KB-2, SD34 KB-2 and GSL1 KB-1 because gravity cores preserve integrity of the uppermost sediment sequence. Preparation for dating required packing freeze-dried lake sediment samples into plastic tubes. Samples taken at $1-\mathrm{cm}$ intervals (from $0-\mathrm{cm}$ to $40-\mathrm{cm}$ for SR1 KB-2, $0-\mathrm{cm}$ to $36.5-$ cm for SD34 KB-2 and $0.5-\mathrm{cm}$ to $26.5-\mathrm{cm}$ for GSL1 KB-1) were prepared for each study lake. After packing, the sediment in the tube was sealed with epoxy and submitted to the

University of Waterloo Environmental Change Laboratory (WATER) for ${ }^{210} \mathrm{~Pb}$ and ${ }^{137} \mathrm{Cs}$ analysis. Gamma spectrometry was used to measure the radioisotope activity needed for the development of the sediment chronologies. Values from samples measured in the gamma spectrometer were coupled with interpolated values to calculate CRS dates for every sample where unsupported ${ }^{210} \mathrm{~Pb}$ was present in SR1 KB-2, SD34 KB-2 and GSL1 KB-1. The depth of supported ${ }^{210} \mathrm{~Pb}$ was interpreted to be reached where ${ }^{210} \mathrm{~Pb}$ values became relatively constant.

In order to constrain sediment chronologies of Russian cores that extend well below the ${ }^{210} \mathrm{~Pb}$ chronology, radiocarbon dating ${ }^{14} \mathrm{C}$ was attempted. Radiocarbon $\left({ }^{14} \mathrm{C}\right)$ has a half-life of 5,568 years and is most often applied for age-dating up to 40,000 years. Lake sediments usually contain telmatic and limnic plant and animal debris that can be collected and dated in order to obtain age control on sedimentary sequences (Björk and Wohlfarth, 2001). For this study, plant macrofossils extracted from SD34 RC-2 at $45-\mathrm{cm}$ and $54-\mathrm{cm}$ core depth were radiocarbon-dated to constrain the sediment chronology below the ${ }^{210} \mathrm{~Pb}$ dated interval.

### 3.2.3 Analysis of Organic Carbon and Nitrogen Content and Stable Isotope Composition

Organic carbon and nitrogen content and stable isotope composition were analysed to reconstruct nutrient dynamics related to hydrologic variability in each study lake. Geochemical characterization of organic matter within lake sediment can reveal organic matter source and supply, cycling of nutrients, and lake productivity throughout time and thus is useful for reconstructing past environmental conditions within lakes (Meyers, 1997; Meyers and Teranes, 2000). The content and isotopic composition of organic
carbon and nitrogen may also be strongly linked to hydrological processes as they have been successfully used in combination with other proxies to reconstruct long-term hydroecological change within the upper Mackenzie River Basin (Wolfe et al., 2008b; Brock et al, 2010; Johnston et al., 2010).

Percent total organic carbon ( $\% \mathrm{C}_{\text {org }}$ ) describes the abundance of organic matter in lake sediments (Meyers and Teranes, 2001). However, only $\sim 50 \%$ of lake sediment organic matter is composed of carbon, making the total organic matter roughly double the $\% \mathrm{C}_{\text {org }}$ value (Meyers and Teranes, 2001). The $\% \mathrm{C}_{\text {org }}$ value is a more sensitive proxy than total organic matter (determined through LOI) because total organic matter content can be inflated by variable amounts of volatile non-carbon components (Meyers and Teranes, 2001). Changes in $\% \mathrm{C}_{\text {org }}$ within a sediment core can be associated with changes in prımary productivity, making it a useful proxy for inferring paleoenvironmental change (Meyers and Teranes, 2001).

Total nitrogen content $(\% \mathrm{~N})$ includes the measurement of both inorganic and organic nitrogen in lake sediment (Talbot, 2001). Nitrogen is an important nutrient for organic productivity. Additionally, nitrogen can act as the limiting nutrient for organic productivity in lakes, meaning changes in lake organic matter production and composition can be influenced by the source and cycling of nitrogen (Talbot, 2001). However, determination of bulk nitrogen by an elemental analyzer does not separate organic and inorganic nitrogen. Inorganic nitrogen typically represents a small fraction of total nitrogen in lake sediments, but can represent a larger proportion of total nitrogen in sediment with low organic content (Meyers, 1997). In such cases, the inorganic fraction can artificially depress the $\mathrm{C} / \mathrm{N}$ ratio (Meyers, 1997).

Expressing lake sediment $\% \mathrm{C}_{\text {org }}$ and $\% \mathrm{~N}$ values as a ratio ( $\mathrm{C} / \mathrm{N}$ ) can indicate the relative contribution of organic matter from terrestrial (allochthonous) or aquatic (autochthonous) sources (Meyers and Teranes, 2001). Typically, organic matter that is aquatic in origin has $\mathrm{C} / \mathrm{N}$ ratıs that are low (4-10), whereas organic matter derived from (cellulose-rich, protein-poor) vascular land plants have high $\mathrm{C} / \mathrm{N}$ ratios of $>20$ (Meyers and Teranes, 2001). However, algal growth under nitrogen-limiting conditions has been shown to cause elevated $\mathrm{C} / \mathrm{N}$ values in highly productive basins (Meyers and Teranes, 2001).

The carbon sotope composition in the organic matter of lake sediments is an important proxy for assessing organic matter sources, reconstructing past productivity, and identifying changes in availability of nutrients in surface waters (Meyers and Teranes, 2001). Stable carbon isotope composition of lake sediment organic matter ( $\delta^{13} \mathrm{C}_{\text {org }}$ ) represents the ${ }^{13} \mathrm{C} /{ }^{12} \mathrm{C}$ ratio and provides an archive of catchment and withinlake processes (Meyers and Teranes, 2001). The carbon isotope composition of aquatic plants is primarily determined by the $\delta^{13} \mathrm{C}$ of the dissolved inorganic carbon source $\left(\delta^{13} \mathrm{C}_{\text {DIC }}\right)$. Processes controlling the $\delta^{13} \mathrm{C}_{\text {DIC }}$ composition include the source and supply of inorganic carbon (e.g., from catchment runoff), ${ }^{13} \mathrm{C}$-enrichment from preferential uptake of ${ }^{12} \mathrm{C}$ by phytoplankton during photosynthesis, isotopic exchange with atmospheric $\mathrm{CO}_{2}$, recycling of ${ }^{13} \mathrm{C}$-depleted $\mathrm{CO}_{2}$ from respiration/decay of water column and bottom sediment organic matter, and uptake of bicarbonate $\left(\mathrm{HCO}_{3}{ }^{-}{ }_{(\mathrm{aq})}\right)$ at elevated pH (Wolfe et al., 2000). Conventional interpretations typically attribute positive shifts in $\delta^{13} \mathrm{C}_{\text {org }}$ to increases in aquatic productivity (McKenzie, 1985; Schelske and Hodell, 1991, 1995;

Meyers and Lallier-Verges, 1999). However, stratigraphic shifts in lake sediment $\delta^{13} \mathrm{C}_{\text {org }}$ may also result from hydrologically-driven changes (Wolfe et al., 1999, 2000)

Nitrogen isotope composition $\left(\delta^{15} \mathrm{~N}\right)$ is commonly used as an indicator of ecosystem productivity, nutrient availabılity, and the source of organic matter (Meyers, 1997; Talbot, 2001). Using $\delta^{15} \mathrm{~N}$ values to identify the source of organic matter is based on the difference between ${ }^{15} \mathrm{~N} /{ }^{/ 4} \mathrm{~N}$ ratios of inorganic nitrogen available to plants in water and on land (Meyers and Teranes, 2001). A $\delta^{15} \mathrm{~N}$ signature depends predominantly on its source. Atmospheric $\mathrm{N}_{2}$ fixed by blue-green algae produce a signature that is lower $(0 \%)$ than non-nitrogen fixing algae (7-10\%) (Meyers and Teranes, 2001). Despite this, interpretation of sedimentary $\delta^{15} \mathrm{~N}$ records is made more difficult than those of carbon, by the complicated dynamıcs of nitrogen biogeochemical cycling (Fogel and Cifuentes, 1993; Bernasconi et al., 1997; Hodell and Schelske, 1998; Brenner at al., 1999; Talbot, 2001)

In order to prepare sediment for organic carbon and nitrogen content and stable isotope analysis, samples taken at $0.5-\mathrm{cm}$ intervals from SR1 KB-2 $(0 \mathrm{~cm}-40 \mathrm{~cm})$, SD34 KB-2 $(0 \mathrm{~cm}-36.5 \mathrm{~cm})$, SD34 RC-2 $(4.5 \mathrm{~cm}-75 \mathrm{~cm})$, GSL1 KB-1 $(0 \mathrm{~cm}-26.5 \mathrm{~cm})$ and GSL1 RC-I $(20 \mathrm{~cm}-100 \mathrm{~cm})$ were treated with a $10 \% \mathrm{HCl}$ wash to dissolve carbonate and rinsed with deionized water to a neutral pH . Samples were then freeze-dried and drysieved through a $500-\mu \mathrm{m}$ mesh to to remove coarse organic matter that may be of terrestrial origin. Organic carbon and nitrogen elemental and stable isotope compositions were measured on the fine fraction using a Continuous Flow Isotope Ratio Mass Spectrometer (CF-IRMS) at the University of Waterloo Environmental Isotope Laboratory (UW-EIL). Elemental organic carbon and nitrogen results are expressed in
percent weight. Stable isotope results are expressed as deviations in per mil (\%) from a standard material. The organic carbon stable isotope composition $\left(\delta^{13} \mathrm{C}\right)$ is measured against Vienna Peedee Belemnite (VPDB) and the nitrogen stable isotope composition $\left(\delta^{15} \mathrm{~N}\right)$ is measured against atmospheric nitrogen (AIR). Analytical uncertainties of $\% \mathrm{C}_{\text {org }}$, $\% \mathrm{~N}, \delta^{13} \mathrm{C}$ and $\delta^{15} \mathrm{~N}$ for SR1 KB-2 are $\pm 0.10 \%, \pm 0.01 \%, \pm 0.08 \%$ and $\pm 0.01 \%$, respectively. Analytical uncertainties of $\% \mathrm{C}_{\mathrm{org}}, \% \mathrm{~N}, \delta^{13} \mathrm{C}$ and $\delta^{15} \mathrm{~N}$ for SD34 KB-2 and RC-2 (combined) are $\pm 0.50 \%, \pm 0.04 \%, \pm 0.12 \%$ and $\pm 0.11 \%$, respectively. Analytical uncertainties of $\% \mathrm{C}_{\mathrm{org}}, \% \mathrm{~N}, \delta^{13} \mathrm{C}$ and $\delta^{15} \mathrm{~N}$ for GSL1 KB-1 and RC-1 (combined) are $\pm 0.50 \%, \pm 0.10 \%, \pm 0.05 \%$ and $\pm 0.40 \%$, respectively. All analytical uncertainties are based on sample replicates.

### 3.2.4 Cellulose Oxygen Isotope Analyses

Oxygen isotope analysis of aquatic plant cellulose extracted from lake sediments can be used to reconstruct lake water oxygen isotope composition, a useful tracer of past hydrological conditions (Edwards and McAndrews, 1989; Edwards, 1993; Wolfe et al., $2001,2007 \mathrm{~b}$ ). Cellulose is a bio-molecule that exists in the cell walls of plants and some algae and is preserved in sediments as algal cells within zooplankton fecal pellets, or as amorphous organic matter (Edwards, 1993). Aquatic cellulose incorporates the oxygen isotope composition of the lake water from which it is formed. The cellulose $\delta^{18} \mathrm{O}$ can be used to reconstruct lake water oxygen-isotope history under the assumption that oxygen isotope fractionation between the lake water and cellulose is constant ( $\alpha_{\text {cell-lw }}=1.028$ ) and is independent of temperature and plant species (Wolfe et al., 2001).

Sediment from SD34 RC-2, GSL1 KB-1 and GSL1 RC-1 were analyzed for cellulose oxygen isotope composition Sediment from SR1 was not analyzed because it was determined that analysis of organic carbon and nitrogen content and stable isotope composition was sufficient for reconstructing past hydrological conditions. SD34 RC-2 was sampled at $0.5-\mathrm{cm}$ resolution $(4.5 \mathrm{~cm}-75 \mathrm{~cm})$ and GSL1 KB-1 $(0 \mathrm{~cm}-26.5 \mathrm{~cm})$ and GSLI RC-1 ( $27 \mathrm{~cm}-100 \mathrm{~cm}$ ) was sampled at $3.0-\mathrm{cm}$ resolution. Cellulose extraction involved several steps (Wolfe et al., 2001, 2007b). Acid-washing to remove carbonate and sieving to separate coarse and fine fractions (see Analysis of Organic Carbon and Nitrogen Content and Stable Isotope Composition) were performed first. Solvent extraction, bleaching, and alkaline hydrolysis were performed on the fine fraction to remove non-cellulose organic material. Next, removal of iron and manganese oxyhydroxides was completed through hydroxylamine leaching, followed by heavyliquid density separation using sodium polytungstate to separate the cellulose fraction from the minerogenic residue. Cellulose oxygen isotope composition was measured using standard methods (Wolfe et al., 2007b) by CF-IRMS at the UW-EIL. Oxygen isotope results were expressed as $\delta$-values, which represent deviations in per mil (\%) from the Vienna-Standard Mean Ocean Water (VSMOW) standard for oxygen. Analytical uncertainties for SD34 RC-2, GSL1 KB-1 and GSL1 RC-1 were $\pm 0.19 \%, \pm 0.72 \%$, and $\pm 0.43 \%$, respectively, based on sample replicates.

## Chapter 4-Results and Interpretation

### 4.1 SR1

### 4.1.1 Core Description

Visual observations of the SR1 KB-2 sediment core prior to field sectioning revealed two distinct units. The lower unit extended from the base of the core ( $39.5-\mathrm{cm}$ depth) to $30.5-\mathrm{cm}$ depth and consisted of inorganic-rich, light grey, silty clay sediment. No plant fibres were observed in these lower strata and LOI revealed high percent mineral matter $(78.0 \%$ to $90.0 \%)$ and low organic matter content $(8.1 \%$ to $18.7 \%)$ below $30.5-\mathrm{cm}$ depth (Figure 10). At $30.5-\mathrm{cm}$ depth there was an abrupt contact where sediment changed from light grey silty clay to dark brown organic sediment (Figure 10). A similar silty clay organic contact was observed in the longer Russian core collected from SR1 (SR1 RC-1). The silty clay interval of the Russian core extended from the contact to the base of the core, indicating that this interval extended at least 57 cm below the base of SR1 KB-2. However, the Russian core was not used for analysis because SR1 KB-2 captured the sediment contact and the uppermost sediments extending to the sediment-water interface were obtained.

The upper strata in SR1 KB-2 consisted of dark brown organic sediment and extended from $30.5 \mathrm{~cm}-0 \mathrm{~cm}$. Organic matter content increased towards the top of the core from $19.1 \%$ to $30.1 \%$ and was higher than in the lower unit. The increase in organic content (Figure 10) was coupled with an increase in visible plant fibres towards the top of the core.

Figure 10. Organic matter content and mineral matter values from LOI analysis on SR1 KB-2. An image of SR1 RC-2 is scaled to fit the core depth of SR1 KB-2 in order to highlight the sediment contact at $30.5-\mathrm{cm}$ core depth.

### 4.1.2 Sediment Core Chronology

Total ${ }^{210} \mathrm{~Pb}$ activity for SR1 KB-2 ranged from $0.023 \mathrm{~Bq} / \mathrm{g}$ to $0.134 \mathrm{~Bq} / \mathrm{g}$. Total ${ }^{210} \mathrm{~Pb}$ activity peaked at $3.25-\mathrm{cm}$ midpoint core depth $(0.130 \mathrm{~Bq} / \mathrm{g})$ and then generally declined from $3.25-\mathrm{cm}(0.101 \mathrm{~Bq} / \mathrm{g})$ to $15.25-\mathrm{cm}(0.040 \mathrm{~Bq} / \mathrm{g})$ midpoint core depth (Figure 11a). From $15.25-\mathrm{cm}$ to $39.25-\mathrm{cm}$, values became relatively constant, ranging from $0.023 \mathrm{~Bq} / \mathrm{g}$ to $0.059 \mathrm{~Bq} / \mathrm{g}$. It was estimated that background (i.e., supported) ${ }^{210} \mathrm{~Pb}$ levels were reached at approximately $15.25-\mathrm{cm}$ midpoint depth $(0.040 \mathrm{~Bq} / \mathrm{g})$ where total ${ }^{210} \mathrm{~Pb}$ activity becomes relatively constant. This resulted in a basal Constant Rate of Supply (CRS) ${ }^{210} \mathrm{~Pb}$ date of $\sim 1792 \mathrm{AD}$ at the $15.25-\mathrm{cm}$ depth horizon (Figure $11 \mathrm{a}, \mathrm{b}$ ). SR $1 \mathrm{~KB}-2$ exhibited a well-defined ${ }^{137} \mathrm{Cs}$ peak that corresponded to a CRS ${ }^{210} \mathrm{~Pb}$ date $\sim 1963 \mathrm{AD}$ at the $9.75-\mathrm{cm}$ midpoint depth horizon (Figure $11 \mathrm{a}, \mathrm{b}$ ). The dating of the ${ }^{137} \mathrm{Cs}$ peak to $\sim 1963 \mathrm{AD}$ corresponds to the maximum ${ }^{137} \mathrm{Cs}$ fallout due to above-ground nuclear bomb testing. The dating of the ${ }^{137} \mathrm{Cs}$ peak to $\sim 1963 \mathrm{AD}$ and $\mathrm{a}{ }^{210} \mathrm{~Pb}$ background value of 0.040 $\mathrm{Bq} / \mathrm{g}$, similar to values determined for cores from the upstream PAD (Wolfe et al., 2005, 2008b) suggests that modeled CRS dates for SR1 KB-2 are robust. The mean sampling resolution for SR1 KB-2 for the CRS modeled dates is $\sim 15.4$ years per cm .

Sediment core chronology below unsupported ${ }^{210} \mathrm{~Pb}$ levels in SR1 KB-2 was extrapolated using a linear regression of the cumulative dry mass and CRS modeled ${ }^{210} \mathrm{~Pb}$ dates through the $0-\mathrm{cm}$ to $14.25-\mathrm{cm}$ interval. The $0-\mathrm{cm}$ to $15.25-\mathrm{cm}$ interval (where supported levels of ${ }^{210} \mathrm{~Pb}$ were estimated to be reached) was not used to extrapolate dates down-core because samples from $14.75-\mathrm{cm}$ and $15.25-\mathrm{cm}$ midpoint depth spanned time intervals ( -34 and 102 years, respectively) that were significantly larger than the average interval for CRS modeled dates above $14.25-\mathrm{cm}$ midpoint depth ( $\sim 3.0$ years) and were
most likely the result of the large peak in ${ }^{210} \mathrm{~Pb}$ concentration observed at $15.25-\mathrm{cm}$ depth. These values are likely over-estimated and were deemed less reliable. This resulted in a date of $\sim 1784 \mathrm{AD}$ at the observed sediment contact at 30.5 cm and a basal date of $\sim 1546$ AD (39.25-cm midpoint depth) for SR1 KB-2 (Figure 11b). Below the 30.5 cm horizon, there is marked change in the average resolution of extrapolated dates from $8.3 \mathrm{yrs} / \mathrm{cm}$ to $25.4 \mathrm{yrs} / \mathrm{cm}$. A decrease in the resolution of extrapolated dates indicates a slower sedimentation rate below the sediment contact at $30.5-\mathrm{cm}$ (Figure 11b). Because the extrapolation is based on CRS values from the organic sediment above the contact, there is less confidence in the chronology below the contact.

Figure 11 a) Activity profiles of ${ }^{2 / 19} \mathrm{~Pb}$ and ${ }^{137} \mathrm{Cs}$ in $\mathrm{Bq} / \mathrm{g}$ for SR1 KB-2 Dashed grey line denotes background levels of supported ${ }^{2 / 4} \mathrm{~Pb} \quad$ b) $S R 1$ sediment core chronology based on the Constant Rate of Supply (CRS) model, extrapolated down core for $K B-2$ using a linear regression of cumulative dry mass and CRS dates through the 0 cm to $1475-\mathrm{cm}$ interval

### 4.1.3 Geochemical Stratigraphy

## Assessment of the Inorganic Nitrogen Fraction: Correction for C/N Ratios

Evaluation of inorganic nitrogen is important because, if present, it can depress calculation of $\mathrm{C} / \mathrm{N}$ ratios and lead to incorrect interpretations of this important metric. Talbot (2001) suggested that inorganic nitrogen can be detected by plotting percent nitrogen (on the $y$-axis) versus percent organic carbon (on the x -axis) and determining the $y$-intercept of the regression line. If the $y$-intercept of the regression line passes through the $y$-axis at a positive value, percent nitrogen is present in excess of percent organic carbon and the positive $y$-intercept value can be used as an estimate to correct for the presence of inorganic nitrogen. Because of the significant change in sediment composition at the visible contact in SR1 KB-2, values from above and below the contact were plotted separately to assess the presence of inorganic nitrogen. Above the visible contact ( $\sim 1784 \mathrm{AD}$ to $\sim 2007 \mathrm{AD}$ ), the linear regression intercepts the x -axis indicating that organic carbon is present in excess of nitrogen and that bulk nitrogen values from this interval do not need correction. In contrast, below the visible sediment contact ( $\sim 1546$ AD to $\sim 1784 \mathrm{AD}$ ), the linear regression intercepts the $y$-axis at $0.030 \%$ (Figure 11). The $95 \%$ confidence interval for $\sim 1546 \mathrm{AD}$ to $\sim 1784 \mathrm{AD}$ is relatively narrow and closely follows the regression line (Figure 12). Therefore, a correction factor of $0.030 \%$ was applied to bulk N values from this interval. The correction resulted in increases to $\mathrm{C} / \mathrm{N}$ ratios below the contact ranging in value from 0.6 to 1.8 . The entire corrected geochemical record is shown in Figure 13.

Figure 12 Percent nitrogen and percent organic carbon cross-plot of SR1 KB-2 Solid lines denote linear regression lines Note that for the interval below the visible contact ( $\sim 1546$ AD to $\sim 1784$ AD), the linear regression line intersects the $y$-axis The value of the $y$-intercept indicates the average amount of inorganic nitrogen for this interval (Talbot, 2001) Dotted lines denote the $95 \%$ confidence intervals for above and below the visible contact

## Geochemical Results and Interpretation

Organic content and carbon and nitrogen elemental and stable isotope analysis have been used to identify four stratigraphic zones in the SR1 KB-2 sediment core (Figure 13). These zones were determined based on observed changes in the geochemical proxies. The transition from Zone 1 to 2 is based on changes in organic carbon, organic nitrogen, $\delta^{13} \mathrm{C}_{\text {org }}$ and $\delta^{15} \mathrm{~N}$. The visible contact in the sediment was not used to establish Zone 2 because changes in most parameters occurred above this horizon. Zone 3 was established at changes in the trends of $\delta^{13} \mathrm{C}_{\mathrm{org}}, \delta^{15} \mathrm{~N}$ and $\mathrm{C} / \mathrm{N}$ ratio and Zone 4 was based on a change in $\delta^{13} \mathrm{C}_{\text {org. }}$. These zones are described and interpreted below.

Figure 13 Geochemical records for SRI KB-2 showing a) organic carbon content, b) organic mitrogen content (light grey line denotes uncorrected values), c) $\delta^{3} C_{\text {org, }}$, d) $\left.\delta^{15} N, e\right) C / N$ (dark grey line denotes values before $N$ correction) and f) organic matter content Dashed lines distinguish different stratigraphic zones

Zone 1 ( $\sim 1546$ AD to $\sim 1818$ AD)
In Zone 1, organic matter content was relatively variable in comparison to higher in the core, and gradually increased from $8.1 \%$ to $28.6 \%$. The organic carbon and nitrogen contents in Zone 1 were the lowest in the record ranging from $2.6 \%$ to $10.2 \%$ and $0.22 \%$ to $0.81 \%$, respectively. Values showed little variability and increased slightly within the zone. $\delta^{13} \mathrm{C}_{\text {org }}$ values ranged narrowly and declined within Zone 1 from $-28.0 \%$ to $27.4 \% . \delta^{15} \mathrm{~N}$ values ranged from $0.5 \%$ to $1.3 \%$ and were considerably more variable than $\delta^{15} \mathrm{~N}$ values in other zones. $\delta^{15} \mathrm{~N}$ values decreased slightly within Zone 1 , but represented some of the highest values in the record. After correcting for the presence of inorganic nitrogen, the $\mathrm{C} / \mathrm{N}$ ratios ranged from 11.4 to 13.9 and were among the most variable and highest in the record. $\mathrm{C} / \mathrm{N}$ ratios increased gradually throughout Zone 1 . The
visible stratigraphic contact ( 30.5 cm ) observed in the sediment was located near the top of Zone 1.

The high $\mathrm{C} / \mathrm{N}$ ratios observed in Zone 1 may be associated with an allochthonous source of organic matter because they are slightly higher (>11) than values that are typically aquatic in origin (4-10) (Meyers and Teranes, 2001). High $\delta^{15} \mathrm{~N}$ values may also suggest a terrestrial supply of organic material as values in Zone $1(0.5 \%$ to $1.3 \%)$ are similar to the $\delta^{15} \mathrm{~N}$ signature of land plants ( $\sim 0.5 \%$ ) (Meyers and Teranes, 2001). If the source of organic material to SR1 is indeed allochthonous, organic matter content, organic carbon content, organic nitrogen content and $\delta^{13} \mathrm{C}_{\text {org }}$ values are representative of organic material from outside the basin and therefore, cannot be used as indicators of aquatıc productivity within Zone 1 .

Zone 2 (~1818 AD to $\sim 1863$ AD)
In Zone 2, organic matter content ranged from 19.1\% to $24.4 \%$. Values showed little variability and remained relatively constant within the zone. The organic carbon and nitrogen contents ranged narrowly from $10.1 \%$ to $11.2 \%$ and $0.82 \%$ to $0.90 \%$, respectively. $\delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-28.4 \%$ to $-27.7 \%$ in Zone 2 with little variability (similar to Zone 1 ). $\delta^{13} \mathrm{C}_{\text {org }}$ values decreased steadily (from $-27.9 \%$ to $28.3 \%$ ) until $\sim 1848 \mathrm{AD}$ at a rate $(-0.22 \%$ /year $)$ greater than that of Zone $1(-$ $0.0024 \% /$ year). From $\sim 1848 \mathrm{AD}$ to the top of Zone $2, \delta^{13} \mathrm{C}_{\text {org }}$ values increased steadily from $-28.3 \%$ to $-27.7 \%$ o. $\delta^{15} \mathrm{~N}$ values ranged from $0.06 \%$ to $0.96 \%$ showing little variability. With the onset of Zone $2, \delta^{15} \mathrm{~N}$ values declined at a faster rate than Zone 1 (from $0.96 \%$ to $0.15 \%$ ). $\mathrm{C} / \mathrm{N}$ ratios ranged from 11.5 to 12.4 , remaining relatively high,
similar to Zone 1. Values were less variable than Zone I, and remained relatively constant until $\sim 1851 \mathrm{AD}$, after which values decreased to the top of the zone (from 12.4 to 11.5).

High C/N ratios until $\sim 1851$ AD had a similar range (11.8 to 12.4) to Zone 1 (11.4 to 12.6) suggesting the dominant source of organic material in Zone 2 remained allochthonous. However, after $\sim 1851, \mathrm{C} / \mathrm{N}$ ratios decreased to the top of the zone. Values became closer (11.5) to those of aquatic origin (4-10) (Meyers and Teranes, 2001) suggesting a possible shift in the dominant source of organic material from allochthonous to autochthonous. A shift in organic material source in Zone 2 may also be supported by decreasing $\delta^{15} \mathrm{~N}$ values throughout the zone. $\delta^{15} \mathrm{~N}$ values that approach zero by the top of Zone 2 are similar to values produced by nitrogen-fixing algae ( $\sim 0 \%$ ) and may suggest increased aquatic productivity towards the top of Zone 2 (Meyers and Teranes, 2001). $\delta^{13} \mathrm{C}_{\text {org }}$ values that increase towards the top of Zone 2 also support an increase in aquatic productivity as increasing $\delta^{13} \mathrm{C}_{\text {org }}$ values are commonly associated with greater in-lake productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). As well, in Zone 2, organic matter content, organic carbon content and organic nitrogen content were consistently higher than observed in Zone 1, consistent with an increase in aquatic productivity

Zone 3 (~1863 AD to ~1953 AD)
In Zone 3, organic matter content ranged from $21.2 \%$ to $26.7 \%$. Values showed little variability (similar to Zone 2) and increased throughout the entire zone. Organic carbon and organic nitrogen content narrowly ranged between $10.1 \%$ to $11.8 \%$ and $0.9 \%$ to
$1.2 \%$, respectively, remainıng relatively constant throughout Zone 3 Outlying values were observed at $\sim 1956 \mathrm{AD}\left(19.5 \%\right.$ for $\% \mathrm{C}_{\text {org }}$ and $18 \%$ for $\left.\% \mathrm{~N}_{\text {org }}\right) . \delta^{13} \mathrm{C}_{\text {org }}$ values in Zone 3 ranged from $-27.6 \%$ to $-27.2 \%$ and are considerably more variable than the lower two zones. $\delta{ }^{13} \mathrm{C}_{\text {org }}$ values fluctuate throughout the zone and are the highest values in the sediment core. $\delta^{15} \mathrm{~N}$ values ranged from $-0.28 \%$ to $0.07 \%$ and were more variable than Zone $2 . \delta^{15} \mathrm{~N}$ values remained relatively constant throughout the zone. $\mathrm{C} / \mathrm{N}$ ratios ranged narrowly from 10.6 to 11.2 and were lower than the lower two zones. Values remained constant throughout Zone 3.

In Zone 3, lower $\mathrm{C} / \mathrm{N}$ ratios than the previous two zones (10.6 to 11.2) represent values similar to organic matter that is aquatic in origin (4-10) (Meyers and Teranes, 2001). This suggests that the dominant source of organic matter deposition in SR1 throughout Zone 3 is autochthonous. Autochthonous deposition of organic matter is supported by low $\delta^{15} \mathrm{~N}$ values (close to $0 \%$ ) throughout the zone. These values are similar to those produced by nitrogen-fixing algae and suggest nitrogen-limiting conditions within SR1 as a result of high primary productivity, similar to studies elsewhere (Brenner et al., 1999; Talbot and Laerdal, 2000). Additionally, $\delta^{13} \mathrm{C}_{\mathrm{org}}$ values in Zone 3 are the highest in the SR1 record. Trends of increasing $\delta^{13} \mathrm{C}_{\text {org }}$ values are conventionally interpreted as an indicator of increased aquatic productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). High values in organic matter content, organic carbon content and organic nitrogen content are consistent with deposition of organic material from high aquatic productivity; however these values may also represent a reduced flux of inorganic sediment to SR1.

Zone 4 (~1953 AD to $\sim 2007 \mathrm{AD}$ )
In Zone 4, organic matter content ranged from $25.1 \%$ to $30.5 \%$. Values ranged narrowly, gradually increasing to the top of the core. Organic carbon and nitrogen content were relatively variable and increased from $11.7 \%$ to $14.3 \%$ and $1.1 \%$ to $1.4 \%$, respectively. These values were the highest in the stratigraphic record. $\delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-28.9 \%$ to $-27.7 \%$ and were the most variable in the $\delta^{13} \mathrm{C}_{\text {org }}$ record. Values gradually decreased towards the top of Zone 4 from $-27.7 \%$ to $-28.4 \%$. $\delta^{15} \mathrm{~N}$ values in Zone 4 ranged from $-0.30 \%$ to $0.20 \%$ and were similarly variable as in Zone 3. Values increased very gradually from $-0.06 \%$ to $-0.09 \%$ to the top of the record. $\mathrm{C} / \mathrm{N}$ values ranged from 9.9 to 11.2 and showed little variability. Values decreased at the base of Zone 4 (from 10.2 to 9.9 ) and then increased from 9.9 to 11.1 until $\sim 1979 \mathrm{AD}$. C/N ratios ranged narrowly between 10.4 and 10.9 from $\sim 1979 \mathrm{AD}$ to the top of the core.

Throughout Zone $4, \mathrm{C} / \mathrm{N}$ ratios remained close to 10 , indicating that the dominant source of organic matter had not changed from Zone 3 and remained autochthonous. Similarly, $\delta^{15} \mathrm{~N}$ values remained close to zero $(-0.3 \%$ to $0.2 \%)$ suggesting that nitrogen remained limited throughout Zone 4. Continued autochthonous deposition of organic matter and high aquatic productivity are consistent with continued high organic matter content, high organic carbon content and high organic nitrogen content at the top of the core. However, applying conventional interpretation of productivity-driven changes in $\delta^{13} \mathrm{C}_{\text {DIC }}$ to decreasing $\delta^{13} \mathrm{C}_{\text {org }}$ values within Zone 4 is inconsistent with high productivity indicated by all other parameters. This suggests that other factors may have caused a change in the $\delta^{13} \mathrm{C}_{\text {org }}$ values.

### 4.2 SD34

### 4.2.1 Core Description

In order to maximize length and integrity of the SD34 sediment record, SD34 KB-2 and SD34 RC-2 were aligned and analyzed. Results from LOI analysis indicated that alignment could be achieved by shifting the SD34 RC-2 record down so that the top was positioned at $4.5-\mathrm{cm}$ core depth (Figure 14). Between $39.0-\mathrm{cm}$ and $12.5-\mathrm{cm}$, the organic matter content profiles diverge slightly, offset by as much as $\sim 10 \%$ (Figure 14). The offset in organic content between SD34 KB-2 and RC-2 could be related to the slightly different coring locations. The overlap indicates that SD34 RC-2 was missing the uppermost 4.5 cm of sediment and that it spanned 75.5 cm to 4.5 cm .

Visual observations of SD34 RC-2 revealed an abrupt contact in the sediment core at $62.5-\mathrm{cm}$ depth, which was not observed in the shorter KB-2 gravity core (Figure 13). From the base of the core to 62.5 cm , the sediment was light brown silty clay, lacking any distinguishable plant material. Similar to the basal sediment of SR1 KB-2, sediment below $62.5-\mathrm{cm}$ core depth in SD34 RC-2 was very dense and had the lowest percent organic matter values in the core ( $5.4 \%$ to $17.6 \%$ ) (Figure 14). From 62.5 cm to 4.5 cm in SD34 RC-2, sediment was darker brown and composed of organic-rich material including many visible plant fibres (Figure 13). Organic matter content values were considerably higher through this interval and increased from $20.3 \%$ to $66.5 \%$ to the top of the core (Figure 14). The entire length of SD34 KB-2 was composed of dark brown sediment similar to SD34 RC-2. There was an increase in organic matter content (from 30.0\% to $85.0 \%$ ) towards the top of the core similar to the upper sediment of SD34 RC-2.

However, there are two very low organic matter content values at $1 \mathrm{~cm}(16.9 \%)$ and 0.5
$\mathrm{cm}(27.9 \%)$ core depth in SD34 KB-2 (Figure 14) that are not accompanied by any observable sedimentary evidence of change.

Figure 14 Correlation between SD34 RC-2 and SD34 KB2 using organic matter content values from LOI analysis. Top of SD34 RC-2 overlaps SD34 KB-2 at 4.5-cm core depth. An image of SD34 RC-2 core prior to sectioning is scaled to fit the core depth axis. A second image shows the contact close up. Dashed line denotes visible sediment contact at $\sim 62.5-\mathrm{cm}$ core depth.

### 4.2.2 Sediment Core Chronology

Total ${ }^{210} \mathrm{~Pb}$ activity for SD34 KB-2 ( 38 cm to 0 cm ) ranged from $0.015 \mathrm{~Bq} / \mathrm{g}$ to 0.325 $\mathrm{Bq} / \mathrm{g}$ and the ${ }^{210} \mathrm{~Pb}$ activity profile generally declined from 0 cm to 15.25 cm (Figure 15 a ). Below $15.25-\mathrm{cm}$ midpoint depth, ${ }^{210} \mathrm{~Pb}$ activity became relatively constant ranging between $0.015 \mathrm{~Bq} / \mathrm{g}$ and $0.044 \mathrm{~Bq} / \mathrm{g}$. Supported ${ }^{210} \mathrm{~Pb}$ levels were estimated to be reached at approximately $15.25-\mathrm{cm}$ midpoint depth $(0.030 \mathrm{~Bq} / \mathrm{g})$. This resulted in a basal Constant Rate of Supply (CRS) ${ }^{210} \mathrm{~Pb}$ date of $\sim 1856$ AD at $15.25-\mathrm{cm}$ midpoint depth, providing a mean sampling resolution of 5.0 years from 0 cm to 15.25 cm (Figure 15b). Despite a broad but relatively well-defined ${ }^{137} \mathrm{Cs}$ peak at $7.25-\mathrm{cm}$ midpoint depth, this occurs at a CRS ${ }^{210} \mathrm{~Pb}$ date of $\sim 1980 \mathrm{AD}, \sim 17$ years after peak fallout from above-ground nuclear bomb testing. This suggests diffusion of ${ }^{137} \mathrm{Cs}$ has modified the peak position in the sediment profile of SD34 KB-2. Diffusion of ${ }^{137} \mathrm{Cs}$ can occur in sediment with high organic matter content such as SD34 KB-2 (Figure 14) (Longmore, 1982; Foster et al., 2006). Diffusion has also been invoked as a process possibly influencing ${ }^{137} \mathrm{Cs}$ activity profiles in paleolimnological studies from the upstream PAD (Hall et al., 2004).

Figure 15 a) Activity profiles of ${ }^{2 / 1} \mathrm{~Pb}$ and ${ }^{137} \mathrm{Cs}$ in Bq/g for SD34 KB-2, dashed grey line denotes background levels of supported ${ }^{21 \prime} \mathrm{~Pb} \quad$ b) SD34 sediment core chronology based on the Constant Rate of Supply (CRS) model, extrapolated down core for both KB-2 and RC-2 Median probability ${ }^{14} \mathrm{C}$ dates of two seed samples are indicated

Sediment chronology below unsupported ${ }^{210} \mathrm{~Pb}$ levels in SD34 KB-2 $(14.75 \mathrm{~cm}$ to 38 cm ) was extrapolated using a linear regression of the cumulative dry mass and CRS modeled ${ }^{210} \mathrm{~Pb}$ dates through the 0 cm to 14.25 cm interval, resulting in a basal date of $\sim 1496$ AD for SD34 KB-2 at $37.75-\mathrm{cm}$ midpoint depth (Figure 15b). Samples from 0 cm to 14.25 cm midpoint depth were used and not 0 cm to 15.25 cm (where supported levels of ${ }^{210} \mathrm{~Pb}$ were estimated to be reached) as samples from 14.75 cm to 15.25 cm spanned relatively large time intervals ( $\sim 23-58$ years) that were likely over estimated and deemed less reliable (Figure 15b). The chronology of SD34 was extended to include SD34 RC-2 ( $37.75-\mathrm{cm}$ to $7525-\mathrm{cm}$ midpoint depth) using a linear regression of extrapolated dates through the $14.75-\mathrm{cm}$ to $37.75-\mathrm{cm}$ interval of SD34 KB-2. This yielded a date of $\sim 998$ AD for the observed sediment contact at 62.5 cm and a basal core date of $\sim 762 \mathrm{AD}$ at $75.25-\mathrm{cm}$ midpoint depth (Figure 15b) Based on this analysis, the sediment record for SD34 spans from $\sim 762$ AD to $\sim 2007$ AD ( $\sim 1245$ years) (Figure 15b). However, because the abrupt change in sediment characteristics below the contact is likely accompanied by a change in sedimentation rate, there is increased uncertainty in sediment age below $62.75-\mathrm{cm}$ midpoint core depth.

Radiocarbon $\left({ }^{14} \mathrm{C}\right)$ dating of two macrofossil samples (seeds from the aquatic plant Potamogeton) from SD34 RC-2 taken from organic sediment above the $62.5-\mathrm{cm}$ depth contact resulted in calibrated median probability ${ }^{14} \mathrm{C}$ dates of $649 \mathrm{AD}(42.25-\mathrm{cm}$ midpoint core depth) and 173 AD ( $54.25-\mathrm{cm}$ midpoint core depth) (Table 3, Figure 15b). These dates are considerably older than the corresponding extrapolated ${ }^{210} \mathrm{~Pb}$ dates ( $\sim 815$ years at 45.25 cm and $\sim 1018$ years at 54.25 cm depth) (Figure 15 b ). Constraining the SD34 ${ }^{210} \mathrm{~Pb}$ chronology using these ${ }^{14} \mathrm{C}$ dates would require a sedimentation rate
substantially slower $(\sim 0.023 \mathrm{~cm} /$ year $)$ than the one based on ${ }^{210} \mathrm{~Pb}$ extrapolation $(0.061$ $\mathrm{cm} /$ year). The sedimentation rate based on ${ }^{210} \mathrm{~Pb}$ extrapolation ( $0061 \mathrm{~cm} /$ year) is also similar to average sedimentation rates of other closed-drainage basins upstream in the PAD $(0.069,0.056$, and $0.069 \mathrm{~cm} /$ year for PAD 5, 9 and Bustard Island North Pond, respectively; Wolfe et al., 2008a). Additionally, observations of the SD34 RC-2 core above the contact reveal no noticeable change in sediment appearance and no evidence of sediment loss due to erosion (Figure 14). Therefore, a marked change in sedimentation rate ( $\sim 3$ times slower) below $15.75-\mathrm{cm}$ is unlikely. Thus, it was concluded that the samples used for radiocarbon $\left({ }^{14} \mathrm{C}\right)$ dating were significantly older than the sediment matrix. For this reason, the radiocarbon dates were dismissed and the extrapolated ${ }^{210} \mathrm{~Pb}$ dates were determined to be most reliable for constructıng the sediment core chronology

Table 3 Results of seed samples from SD3\& RC-2 submitted for radıocarbon dating with 2 sigma standard deviatıons (95\% probability) Radıocarbon dates were calibrated to calendar years before present using the program CALIB (version 60 ) (Stuiver and Reimer, 1993) with the calibration data set of Reimer et al (2004)

### 4.2.3 Geochemical Stratigraphy

Assessment of the Inorganic Nitrogen Fraction: Correction for C/N Ratios
Using methods outlined by Talbot (2001), percent nitrogen and percent organic carbon were plotted against each other to determine the quantity of inorganic nitrogen for SD34 KB-2 and RC-2. Because of the significant change in sediment composition at the visible contact in SD34 RC-2, values from above and below the contact were plotted separately. Above the visible contact ( $\sim 998 \mathrm{AD}$ to $\sim 2007 \mathrm{AD}$ ), the linear regression intercepts the x -axis indicating that bulk nitrogen values from this interval do not need correction. In contrast, below the visible sedıment contact ( $\sim 762 \mathrm{AD}$ to $\sim 998 \mathrm{AD}$ ), the linear regression intercepts the $y$-axis at $0.041 \%$ (Figure 16). The $95 \%$ confidence interval for values below the visible contact is relatively narrow and closely follows the regression line (Figure 16). Therefore, a correction of $0.041 \%$ was applied to bulk nitrogen values from this interval. The correction resulted in increases to $\mathrm{C} / \mathrm{N}$ ratios below the contact ranging in value from 0.7 to 1.7. The entire corrected geochemical record is shown in Figure 17.

Figure 16 Percent nitrogen and percent organic carbon cross-plot of SD $34 K B-2$ and $R C-2$ Solid lines denote linear regression lines Note that for the interval below the visible contact $(\sim 762$ AD to $\sim 998$ AD), the linear regression line intersects the $y$-axis The value of the $y$ intercept indicates the average amount of inorganic nitrogen for this interval (Talbot, 2001) Dotted lines denote the $95 \%$ confidence intervals for above and below the visible contact

## Geochemical Results and Interpretation

Four stratigraphic zones in the SD34 sediment record (KB-2 and RC-2 cores) have been identified using organic carbon and nitrogen content and elemental and stable isotope analyses (Figure 17). These zones were established based on horizons of change in the geochemical proxies. The transition from Zone 1 to 2 is based on changes in organic matter content, organic carbon content, organic nitrogen content, $\delta^{13} \mathrm{C}_{\text {org }}$ and the $\mathrm{C} / \mathrm{N}$ ratio. These stratigraphic changes lie at the same horizon as the visible contact between silty clay sediment and organic sediment in SD34 RC-2. Zone 3 was established at an abrupt shift in $\delta^{13} \mathrm{C}_{\text {org }}$ values and Zone 4 was established at another prominent shift in $\delta^{13} \mathrm{C}_{\text {org }}$ values. The four zones are described and interpreted below.

Figure 17 Geochemical records for SD34 showing a) percent organic carbon, b) percent organic nitrogen (light grey line denote uncorrected values), c) $\delta^{3} C_{\text {orr, }}$ d) $\delta^{15} N$, e) $C / N$ (dark grey line denotes values before $N$ correction), f) organic matter content, and g) cellulose-inferred lake water $\delta^{\text {/ }} O$ Black line through $\delta^{*} O$ values is a 3-point running mean Dashed lines distinguish different strattgraphic zones SD34 $K B-2$ and $R C-2$ values are overlapped from +5 cm to 8 cm Plotted values through this interval are an average of $K B-2$ and $R C-2$ values

Zone 1 (~762 AD to ~998 AD)
In Zone 1, organic matter content narrowly ranged from $6.0 \%$ to $20.3 \%$ and were the lowest in the sedimentary record. Values were initially constant (narrowly ranging from $7.0 \%$ to $9.0 \%$ ), and then gradually increased at $\sim 909 \mathrm{AD}$ from $9.0 \%$ to $20.3 \%$. Similarly, organic carbon and nitrogen content in Zone 1 were the lowest in the record ranging from $3.0 \%$ to $9.6 \%$ and $0.3 \%$ to $1.3 \%$, respectively. Both parameters gradually increased upcore. Zone 1 included some of the highest $\delta^{13} \mathrm{C}_{\text {org }}$ values in the record ranging from $25.9 \%$ to $-24.2 \%$. Values in Zone 1 had a relatively narrow range in comparison to values higher in the core and exhibited a gradual increase towards the top of the zone (from $-25.3 \%$ to $-24.2 \%$ ). $\delta^{15} \mathrm{~N}$ values ranged from $0.6 \%$ to $1.3 \%$ and were the lowest in the entire record. The $\mathrm{C} / \mathrm{N}$ ratios ranged from 12.0 to 12.6 and were relatively constant
throughout Zone 1. Cellulose-inferred lake water $\delta^{18} \mathrm{O}$ values ( $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ ) ranged from $22.0 \%$ to $-17.7 \%_{0}$ and were highly variable throughout Zone $1 . \delta^{18} \mathrm{O}_{\mathrm{lw}}$ values in Zone 1 were among the lowest in the record.
$\mathrm{C} / \mathrm{N}$ ratios in Zone l were higher than values of organic material aquatic in origin (410 ), suggesting that the organic material deposited on the lake bed was predominantly allochthonous (Meyers and Teranes, 2001). $\delta^{15} \mathrm{~N}$ values in Zone 1 may also indicate a terrestrial supply of organic material as values $(0.6 \%$ to $1.3 \%)$ are similar to the $\delta^{15} \mathrm{~N}$ signature of land plants $(\sim 0.5 \%)$ (Meyers and Teranes, 2001). $\delta^{13} \mathrm{C}$ values in Zone 1 were among the highest in the SD34 sediment record. Conventionally, elevated $\delta^{13} \mathrm{C}$ values are associated with elevated aquatic productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). Elevated aquatic productivity is not consistent with physical observations of the sediment below the visible contact, low organic matter, low percent organic carbon and low percent organic nitrogen or with the interpretation of $\mathrm{C} / \mathrm{N}$ ratios. Therefore, the $\delta^{13} \mathrm{C}_{\text {org }}$ signature in Zone 1 is most likely reflecting the allochthonous source of organic material being deposited in SD34. An allochthonous source of organic material may have compromised the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values in Zone 1. However, the raw cellulose values within Zone 1 range from $5.4 \%$ to $9.6 \%$ (Appendix E) and are significantly lower than those expected for terrestrial cellulose ( $>20 \%$ ) (e.g., Saurer at al., 1997). Therefore, the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values in Zone 1 do not appear to be compromised by terrestrial organic material and likely reflect the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ signature of SD34.

Zone 2 (~998 AD to ~1292AD)
The transition from Zone 1 to 2 was characterized by changes in many parameters and is also associated with the visible sediment contact in SD34 RC-2. Organic matter content gradually increased within Zone 2 from $20.3 \%$ to $41.9 \%$. Organic carbon content increased from $9.6 \%$ to $22.8 \%$ at a faster rate than Zone 1. In Zone 2, Organic nitrogen content increased from $1.3 \%$ to $1.7 \%$, but at a slower rate than Zone 1 . At the onset of Zone $2, \delta^{13} \mathrm{C}_{\text {org }}$ values abruptly reversed trend and gradually decreased from $-24.8 \%$ to $25.9 \%$. $\delta^{13} \mathrm{C}_{\text {org }}$ values through the $\sim 1214 \mathrm{AD}$ to $\sim 1292 \mathrm{AD}$ interval were among the lowest in the sediment record (between $-25.9 \%$ and $-25.7 \%$ ). $\delta^{15} \mathrm{~N}$ values gradually increased throughout Zone 2 from $0.7 \%$ to $1.1 \%$. $\mathrm{C} / \mathrm{N}$ ratios ranged from 11.9 to 13.4 and increased throughout the zone. $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values ranged from $-22.4 \%$ to $-16.6 \%$ and were highly variable.

The increase in $\mathrm{C} / \mathrm{N}$ ratios throughout Zone 2 could indicate that the source of the organic material is allochthonous. However, the change in sediment composition from inorganic to organic at the onset of Zone 2 coupled with increases in organic matter, organic carbon and organic nitrogen contents throughout the zone may alternatively suggest that deposition of organic matter in SD34 is associated with increased aquatic productivity. Teranes and Bernasconi (2000) have documented increases in productivity being accompanied by higher $\delta^{15} \mathrm{~N}$ values. Thus, increasing $\delta^{15} \mathrm{~N}$ values in Zone 2 may further indicate increased aquatic productivity above the visible sediment contact. Increased aquatic productivity contradicts the conventional $\mathrm{C} / \mathrm{N}$ interpretation of relatively high $\mathrm{C} / \mathrm{N}$ ratios reflecting allochthonous organic material deposition, indicating that elevated $\mathrm{C} / \mathrm{N}$ values in Zone 2 may alternatively be the result of diagenetic alteration.
$\mathrm{C} / \mathrm{N}$ ratios derived from algae can increase during sedimentation in lakes having high productivity due to active microbial denitrification of organic matter (Meyers and Teranes, 2001). Therefore, because of strong evidence from a variety of parameters, the organic material source for SD34 throughout Zone 2 is interpreted to be autochthonous despite increasing $\mathrm{C} / \mathrm{N}$ ratios.

Conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ does not agree with the above interpretation of the other geochemical parameters. With the onset of Zone $2, \delta^{13} \mathrm{C}_{\text {org }}$ values began to decrease, a trend that is usually interpreted as a decline in productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). As a result, the conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ is likely not appropriate for Zone $2 . \delta^{18} \mathrm{O}_{\mathrm{lw}}$ values in Zone 2 remained highly variable and difficult to interpret. However, low $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values at the onset of Zone 2 may indicate periods of low evaporative enrichment.

Zone 3 (~1292 AD to ~1918 AD)
In Zone 3, organic matter content gradually increased throughout the zone from $41.9 \%$ to $63.2 \%$. Organic carbon and nitrogen contents ranged from $22.8 \%$ to $35.4 \%$ and $1.8 \%$ to $2.7 \%$, respectively. Both sets of values gradually increased within Zone $3 . \delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-25.3 \%$ to $-24.5 \%$ and were the most variable in the record. The transition from Zone 2 to 3 was associated with an abrupt $+0.8 \%$ shift in $\delta{ }^{13} \mathrm{C}_{\mathrm{org}}$ values ($25.7 \%$ to $-24.9 \%$ ). Values remained high and variable for the duration of the zone. In Zone $3, \delta^{15} \mathrm{~N}$ values increased from $1.2 \%$ to $1.8 \% \mathrm{C} / \mathrm{N}$ ratios ranged from 13.9 to 15.2 with little variability. From the onset of Zone 3 until $\sim 1381$ AD, C/N ratios were relatively constant (ranging from 13.9 to 14.4). There was an abrupt increase in $\mathrm{C} / \mathrm{N}$
ratios (from 14.3 to 15.2 ) between $\sim 1381 \mathrm{AD}$ and $\sim 1390 \mathrm{AD}$, followed by a gradual decrease in values (from 14.1 to 13.6) to the top of the zone. $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values ranged from $20.6 \%$ to $-15.1 \%$ and were highly variable. Despite this, there was a noticeable oscillation in $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values within Zone 3. An interval of low values occurred between $\sim 1607 \mathrm{AD}$ and $\sim 1736 \mathrm{AD}$ with values generally ranging between $-20.6 \%$ to $-19.0 \%$. An interval of high $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values occurred between $\sim 1745 \mathrm{AD}$ and $\sim 1837 \mathrm{AD}$ ranging from $18.5 \%$ to $-15.1 \%$, and included several of the highest $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values in the record.
$\mathrm{C} / \mathrm{N}$ ratios in Zone 3 are higher (13.9 to 15.2) than those aquatic in origin (4-10). Similar to Zone 2, elevated values in Zone 3 may be explained by diagenetic alteration. $\mathrm{C} / \mathrm{N}$ ratios produced by aquatic algae under highly productive conditions can increase during sedimentation due to active microbial denitrification of organıc matter (Meyers and Teranes, 2001). High productivity in Zone 3 is suggested by elevated organic matter deposition as indicated by high organic matter, organic carbon and organic nitrogen contents. High aquatic productivity is further supported by increasing $\delta^{15} \mathrm{~N}$ values in Zone 3. Increased productivity can be accompanied by higher $\delta^{15} \mathrm{~N}$ values as observed by Meyers and Teranes (2000). $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ values in Zone 3 were higher than Zones 1 and 2, possibly indicating that evaporative enrichment had increased.

Zone 4 (~1918 AD to ~2007 AD)
In Zone 4, organic matter content ranged from $59.1 \%$ to $84.9 \%$ with the exception of two outlier values (2004: 16.9\%; 2006: 27.9\%) that are very low. Similar changes are not observed at these horizons in any other proxy. Organic matter content increased throughout the zone from $63.2 \%$ to $84.9 \%$. Organic carbon and nitrogen contents
narrowly ranged from $35.4 \%$ to $41.0 \%$ and $2.7 \%$ to $3.5 \%$, respectively. Values increased throughout Zone 4 with greater rates of increase occurring after $\sim 1980 \mathrm{AD} . \delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-26.6 \%$ to $-25.3 \%$ and are less variable than the previous zone. Values sharply decreased at the onset of Zone 4 from $-25.3 \%$ to $-26.3 \%$ to top of the record. $\delta^{15} \mathrm{~N}$ values gradually increased from $1.8 \%$ to $2.5 \%$. Similar to percent organic carbon and nitrogen values, $\delta^{15} \mathrm{~N}$ values exhibited a greater rate of increase after $\sim 1980 \mathrm{AD} . \mathrm{C} / \mathrm{N}$ values ranged from 11.7 to 13.9 with less variability than Zone 3 and remained relatively constant until $\sim 1980 \mathrm{AD}$. $\mathrm{C} / \mathrm{N}$ ratios declined after $\sim 1980 \mathrm{AD}$ from 13.6 to $11.8 . \delta^{18} \mathrm{O}_{\mathrm{lw}}$ values remained highly variable through this zone ranging from $-19.9 \%$ to $-15.8 \%$ and had no discernable pattern.

Relatively high $\mathrm{C} / \mathrm{N}$ ratios ( 11.7 to 13.9 ) may suggest an allochthonous source of organic material for Zone 4. However, preferential loss of nitrogen from organic matter can cause $\mathrm{C} / \mathrm{N}$ ratios derived from algae to increase (Meyers and Teranes, 2001). As a result, the high $\mathrm{C} / \mathrm{N}$ ratios may be the result of microbial denitrification of organic matter in the lake sediment under highly productive conditions, similar to that observed by Sarazin et al. (1992). Bulk organic, organic carbon and organic nitrogen contents and $\delta^{15} \mathrm{~N}$ values in Zone 4 are all high, suggesting high productivity. $\mathrm{C} / \mathrm{N}$ ratios after $\sim 1980$ AD decreased rapidly and are lower than values at the base of the zone. These values most likely represent $\mathrm{C} / \mathrm{N}$ ratios that have not yet been altered by diagenetic effects inferred lower in the core. Similarly, percent organic matter, percent organic carbon and percent nitrogen all rapidly increase after $\sim 1980 \mathrm{AD}$, possibly indicating that diagenesis has not altered the uppermost sediments.

The lowest $\delta^{13} \mathrm{C}_{\text {org }}$ values occur at the top of Zone 4 with the greatest rates of decrease occurring after $\sim 1980 \mathrm{AD}$, similar to other parameters measured for SD34. The shift to lower values at the onset of Zone 4 would conventionally correspond to decreased productivity, contradicting interpretations of the other geochemical variables. This would suggest that similar to Zone 1 and 2, the conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ values is not appropriate for Zone 4. As well, $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values continued to be highly variable. The range of values in Zone 4 is similar to Zone 3 making any interpretation of hydrologic change based on $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ difficult.

### 4.3 GSL1

### 4.3.1 Core Description

To maximize the length and integrity of the GSL1 sediment record, GSL1 KB-1 and GSL1 RC-1 were aligned and analyzed. The organic matter content profile from GSL1 RC-1 (upper 43.5 cm ) was shifted down by 0.5 cm to achieve the best observed overlap with the organic matter content profile of GSL1 KB-1 ( 0 cm to 26.5 cm ) (Figure 18). This indicated that GSL1 RC-1 was only missing the uppermost 0.5 cm of sediment and the core spanned 0.5 cm to 100 cm of the GSL1 sediment profile (Figure 19). Therefore, overlapping the top of GSL1 RC-1 at 0.5 cm of GSL1 KB-1 generated a $100-\mathrm{cm}$-long sediment record.

The depth interval of 20 cm to 15 cm in GSL1 RC-1 included a large piece of plant material that corresponded with anomalously high and erratic percent organic matter content values (Figure 18). Thus, only GSL1 RC-1 samples below $20-\mathrm{cm}$ depth and GSL1 KB1 samples from 26.5 cm to 0 cm were further analyzed for geochemical
parameters. Percent organic carbon values from this continuous record are used to accompany visual observatıons of the sediment core because LOI (organic content) was only conducted on the uppermost 43.5 cm of GSL1 RC-1.

Visual observations of GSL1 RC-1 revealed a lithologic contact between 73 and 68cm core depth that was gradational, in contrast to the abrupt contact visible in SR1 and SD34 (Figure 18). However, similar to the previously described cores, the gradational contact in GSL1 RC-1 separated two distinct stratigraphic units in the GSL1 sediment profile. The basal sediment ( $100-\mathrm{cm}$ to $73-\mathrm{cm}$ ) was light brown silty clay and absent of plant material. Faintly visible laminations were observed throughout the lower strata (Figure 18) and a change in sediment particle size was observed from $92-\mathrm{cm}$ to $88-\mathrm{cm}$ where sediment was visibly coarser. These sediments are characterized by very low percent organic carbon values ranging from $1.2 \%$ to $4.6 \%$ (Figure 19). At $73-\mathrm{cm}$ core depth, a gradual shift from light brown inorganic material to dark brown organic-rich material was observed. This observation was accompanied by an abrupt increase in percent organic carbon values from $4.6 \%$ to $25.8 \%$ through the 73 cm to 68 cm gradational contact (Figure 19). From 68 cm to 0 cm , sediment was dark brown and composed of organic-rich material including visible plant material that increased in abundance towards the top of the core (Figure 19). These sediments were characterized by high percent organic carbon values ( $30.6 \%$ to $45.2 \%$ ) that increased towards the top of the core (Figure 19).

Figure 18. Correlation between GSL1 RC-1 and GSL1 KB-1 using organic matter content from LOI analysis. Top of GSL1 RC-1 overlaps GSL1 KB-1 at 0.5-cm core depth An image of a tuber which affected the percent organic content values within GSL1 RC-1 is shown at 15 cm to 20 cm

Figure 19 Organic carbon content for GSL1 KB-1 ( 26.5 cm to 0 cm ) and GSL1 RC-1 (100 cm to 20 cm ). The two cores are overlapped between the 20 cm to 26.5 cm interval. An image of GSL1 $R C-1$ prior to sectioning is scaled to fit the core depth axis. A second image shows the contact close up. Grey dashed lines denote visible gradational contact from 73 cm to 68 cm

### 4.3.2 Sediment Core Chronology

Total ${ }^{210} \mathrm{~Pb}$ activity for GSL1 KB-1 ranged from $0.005 \mathrm{~Bq} / \mathrm{g}$ to $0.260 \mathrm{~Bq} / \mathrm{g}$. Values declined from $0.250 \mathrm{~Bq} / \mathrm{g}$ at $0-\mathrm{cm}$ to $0.037 \mathrm{~Bq} / \mathrm{g}$ at $11.75-\mathrm{cm}$ midpoint core depth and become less variable between $12.25-\mathrm{cm}$ and $26.25-\mathrm{cm}$ midpoint core depth (ranging from $0.005 \mathrm{~Bq} / \mathrm{g}$ to $0.023 \mathrm{~Bq} / \mathrm{g}$ ). Supported ${ }^{210} \mathrm{~Pb}$ levels were estimated to be reached where ${ }^{210} \mathrm{~Pb}$ activity becomes constant at $\sim 1225-\mathrm{cm}$ midpoint depth ( $0.018 \mathrm{~Bq} / \mathrm{g}$ ) (Figure 20a). This resulted in a CRS ${ }^{210} \mathrm{~Pb}$ date of $\sim 1860 \mathrm{AD}$ at $12.25-\mathrm{cm}$ midpoint depth and provided a mean sampling resolution of 11.5 years through the $0-\mathrm{cm}$ to $12.25-\mathrm{cm}$ interval (Figure 20b). ${ }^{137}$ Cs values from GSL1 KB-1 lacked a well-defined peak, and instead declined steadily from the top of the core to $12.25-\mathrm{cm}$ midpoint depth (Figure 20a). The absence of a peak likely indicates diffusion of ${ }^{137} \mathrm{Cs}$ which occurs more frequently in organic-rich sediments (Longmore, 1982; Foster et al., 2006) such as those as the top of GSL1 KB-1 (Figure 18). Therefore, ${ }^{137} \mathrm{Cs}$ from GSL1 is unreliable for constraining the sediment core chronology.

Figure 20 a) Activity profiles of ${ }^{2 / 1} \mathrm{~Pb}$ and ${ }^{13^{7}} \mathrm{Cs}$ in $\mathrm{Bq} / \mathrm{g}$ for GSLI KB-1, Dashed grey line denotes supported ${ }^{211} \mathrm{~Pb}$ b) GSL1 sediment core chronology based on the Constant Rate of Supply (CRS) model, extrapolated down-core for both KB-1 and RC-1

A linear regression of the cumulative dry mass and CRS modeled ${ }^{210} \mathrm{~Pb}$ dates through the $0-\mathrm{cm}$ to $1125-\mathrm{cm}$ interval of GSLI KB-1 was used to extrapolate dates below unsupported ${ }^{210} \mathrm{~Pb}$ levels in GSLI KB-1. Dates were extrapolated from $11.25-\mathrm{cm}$ depth to the bottom of the core and not from $12.25-\mathrm{cm}$ where supported levels of ${ }^{210} \mathrm{~Pb}$ were estimated to be reached, as calculated CRS dates for samples from 11.75 cm to 12.25 cm spanned relatively large time intervals ( $\sim 21-35$ years) that ware likely overestimated and were deemed to be less reliable Extrapolation resulted in a basal date of $\sim 1728 \mathrm{AD}$ for the gravity core at $26.25-\mathrm{cm}$ midpoint depth (Figure 20b). Using a linear regression of extrapolated dates through the 11.25 cm to 26.75 cm interval of SD34 KB-1 and midpoint depth, the chronology of GSL1 was extended to include GSL1 RC-1 ( 26.75 cm to 99.75 cm ) This yielded a dated interval of $\sim 1142 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ for the gradational contact observed in the sediment core between $73-\mathrm{cm}$ and $68-\mathrm{cm}$ depth and a basal core date of $\sim 803 \mathrm{AD}$ at $99.75-\mathrm{cm}$ midpoint depth (Figure 20b). Therefore, the sediment record for GSL1 spans from $\sim 803 \mathrm{AD}$ to $\sim 2007 \mathrm{AD}(\sim 1204$ years) (Figure 20b). However, similar to SR1 and SD34, the change in sediment characteristics below the contact is likely accompanied by a change in sedimentation rate, increasing the uncertainty in sediment age below 68 cm .

Radiocarbon ( ${ }^{14} \mathrm{C}$ ) dating was not used to constrain the chronology of GSL1 because there were no plant macrofossils found in the core. Bulk samples were not submitted for ${ }^{14} \mathrm{C}$ dating because the presence of bitumen in the Peace and Athabasca river basins (upstream of the Slave River) has previously resulted in dates that are too old (e.g., Wolfe et al., 2006). Unreliable radiocarbon dates obtained for SD34 coupled with an absence of
reliable dating material resulted in the decision to not attempt radiocarbon dating as a tool for constraining the ${ }^{210} \mathrm{~Pb}$-extrapolated sediment chronology.

### 4.3.3 Geochemical Stratigraphy

## Assessment of the Inorganic Nitrogen Fraction: Correction for C/N Ratios

Because of the significant change in sediment composition at the gradational contact in GSL1 KB-1, percent nitrogen and percent organic carbon values from above, below and within the gradational contact were plotted separately. Above the visible contact ( $\sim 1199 \mathrm{AD}$ to $\sim 2007 \mathrm{AD}$ ), the linear regression intercepts the x -axis indicating that organic carbon is present in excess of nitrogen and that bulk nitrogen values from this interval do not need correction. In contrast, within and below the visible sediment contact ( $\sim 1155 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ and $\sim 803 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ ), linear regressions intercept the y axis at $0.0409 \%$ and $0.0165 \%$, respectively (Figure 21). Although these values are relatively small, the percent organic carbon and nitrogen values are also relatively small, making the correction factor meaningful. The $95 \%$ confidence intervals for $\sim 1155 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ and $\sim 803 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ are very narrow and closely follow the regression line (Figure 21). Therefore, corrections of $0.0409 \%$ and $0.0165 \%$ were applied to bulk N values from within and below the gradational contact, respectively. The correction resulted in increases to $\mathrm{C} / \mathrm{N}$ ratios at the gradational contact ranging in value from 0.3 to 1.3 and below the gradational contact ranging from 0.5 to 3.7. The entire corrected geochemıcal record is shown in Figure 22.

Figure 21 Percent nitrogen and percent organic carbon cross-plot of GSL1 KB and RC-1. Solid lines denote linear regression lines Note that for the interval within ( $\sim 1155 \mathrm{AD}$ to $\sim 1199 \mathrm{AD}$ ) and below ( $\sim 803$ AD to $\sim 1199$ AD) the gradational contact linear regression lines intersect the $y$-axis. The value of the $y$-intercept indicates the average amount of inorganic nitrogen for this interval (Talbot, 2001) Dotted lines denote the $95 \%$ confidence intervals for above and below the visible contact

## Geochemical Results and Interpretation

Assessment of the geochemical results has identified five stratigraphic zones in the GSL1 sediment record including the gradational contact (Figure 22). The transition from Zone 1 to the gradational contact is based on changes in all variables. The gradational contact is characterized by sharp trends in all parameters. Similarly, Zone 2 was based on changes in trend observed in all parameters. The base of Zone 3 is characterized by shifts in $\delta^{13} \mathrm{C}_{\text {org }}, \delta^{15} \mathrm{~N}$ and $\mathrm{C} / \mathrm{N}$ values and Zone 4 was based on changes in trends for $\delta^{13} \mathrm{C}_{\text {org }}$, percent organic carbon and percent organic nitrogen. The four zones and gradational contact interval are described and interpreted below.

Figure 22 Geochemical records for GSLI showing a) percent organic carbon, b) percent organic nitrogen (dark grey line denotes uncorrected values), c) $\delta^{3} C_{\text {ore, }}$ d) $\delta^{3} N$, e) C/N (dark grey line denotes values before $N$ correction), f) cellulose-inferred lake water $\delta$ ' $O$ Dashed lines distinguish different strattgraphic zones GSL1 KB-1 and RC-1 values are overlapped from 20 cm to 27 cm Plotted values through this interval are an average of $K B-1$ and $R C-1$ values

Zone 1 ( $\sim 803$ AD to $\sim 1142 A D$ )
In Zone 1 , organic carbon and nitrogen contents narrowly ranged from $1.5 \%$ to $1.9 \%$ and $0.05 \%$ to $0.19 \%$, respectively. Values were the lowest in the record for both parameters. $\delta^{13} \mathrm{C}_{\text {org }}$ and $\delta^{15} \mathrm{~N}$ values in Zone 1 ranged from $-27.0 \%$ to $-26.0 \%$ and $1.2 \%$, to $2.2 \%$, respectively, with little variability and were the highest in the record. Both proxies remained relatively constant throughout the zone. $\mathrm{C} / \mathrm{N}$ ratios ranged from 13.6 to 19.1 and were highly variable. Values weakly increased towards the top of the zone and were the highest in the record. $\delta{ }^{18} \mathrm{O}_{\mathrm{lw}}$ values are the lowest in the record ranging between $-24.1 \%$ to $-20.2 \%$ and remain relatively constant throughout the zone.

High $\mathrm{C} / \mathrm{N}$ ratios ( $>15$ ) in Zone 1 are higher than those typically produced by aquatic plants ( $<10$ ), suggesting that the dominant source of organic material deposited is allochthonous (Meyers and Teranes, 2001) $\delta^{13} \mathrm{C}_{\text {org }}$ values in Zone 1 were the highest in
the GSLI record. However, the $\delta^{13} \mathrm{C}_{\text {org }}$ signature in Zone 1 is most likely reflecting the $\delta^{13} \mathrm{C}_{\text {org }}$ signature of the allochthonous source of organic material deposited in GSLI and not aquatic productivity. Similarly, low percent organic carbon and nitrogen values may also reflect the allochthonous source of organic material. However, similar to SD34, raw $\delta^{18} \mathrm{O}$ values in Zone 1 (ranging from $3.2 \%$ to $7.2 \%$; Appendix E) are considerably lower than those typically produced by terrestrial plants ( $>20 \%$ ) (e.g., Saurer et al., 1997) suggesting that these values were not compromised by terrestrial organic material and that they do reflect the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ signature of GSL1. Low $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values likely reflect lake water that has undergone minimal evaporative isotopic enrichment.

## Gradational Contact ( $\sim 1142$ AD to $\sim 1199$ AD)

Across the gradational contact, organic carbon and nitrogen contents increased substantially from $3.5 \%$ to $25.8 \%$ and $0.3 \%$ to $1.9 \%$, respectively. $\delta^{13} \mathrm{C}_{\text {org }}$ and $\delta^{15} \mathrm{~N}$ values decreased from $-29.1 \%_{0}$ to $-27.2 \%_{0}$ and $-0.2 \%$ to $1.2 \%$, respectively. $\mathrm{C} / \mathrm{N}$ ratios ranged from 12.7 to 14.4 with less variability than Zone 1 . Values shifted to lower ratios at the onset of the gradational contact and remained relatively constant. $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values within the gradational contact increased from $-21.9 \%$ to $-20.2 \%$.

The gradational contact represents an interval of rapid change within the GSL1 sediment profile. The shift to lower $\mathrm{C} / \mathrm{N}$ ratios is towards values representative of organic material that is aquatic in origin (4-10), indicating a possible change in the dominant source of organic material deposited in the basin from allochthonous to autochthonous (Meyers and Teranes, 2001). However, $\mathrm{C} / \mathrm{N}$ ratios in the gradational contact are still relatively high compared to values typically observed for organic material that is aquatic
in origin. The higher values are most likely the result of nitrogen-limiting conditions, which has been shown to elevate $\mathrm{C} / \mathrm{N}$ ratios (Meyers and Teranes, 2001). Nitrogenlimiting conditions throughout the gradational contact are supported by $\delta^{15} \mathrm{~N}$ values that decrease towards $0 \%$. $\delta^{15} \mathrm{~N}$ values close to $0 \%$ may be associated with high abundances of nitrogen-fixing algae. Increases in percent organic carbon and nitrogen throughout the gradational contact, suggest an increase in aquatic productivity, which is consistent with a high abundance of nitrogen-fixing algae. An autochthonous source of organic material and increased aquatic productivity is consistent with the transition from silty clay to organic sediment observed in the sediment core. As well, increasing $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values may suggest increased evaporative loss of water from GSL1 characteristic of a lake transitioning into an isolated basin. However, conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ values through this interval suggests a decline in productivity, contradicting all other interpretations.

Zone 2 ( $\sim 1199$ AD to $\sim 1577$ AD)
In Zone 2, organic carbon and nitrogen content were more variable than Zone 1 and gradually increased from $25.8 \%$ to $43.2 \%\left(\% \mathrm{C}_{\text {org }}\right)$ and $1.8 \%$ to $2.8 \%(\% \mathrm{~N})$ towards the top of the zone. $\delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-30.2 \%$ to $-29.0 \%$ with little variability. $\delta^{15} \mathrm{~N}$ values in Zone 2 ranged from $-1.1 \%$ to $0.1 \%$ and were more variable than Zone 1. $\mathrm{C} / \mathrm{N}$ ratios increased slightly from 13.3 to 16.0 and were slightly more variable than Zone 2. $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values gradually increased from $-21.0 \%$ to $-16.9 \%$ to the top of the zone.

Despite a slight increase in $\mathrm{C} / \mathrm{N}$ ratios throughout Zone 2, values were consistently lower than Zone 1. This would suggest that the dominant source of organic material
remained unchanged from the gradational contact and was most likely autochthonous. Similar to the gradational contact, $\mathrm{C} / \mathrm{N}$ ratios were likely elevated due to nitrogenlimiting conditions. $\delta^{15} \mathrm{~N}$ values in Zone 2 were close to $0 \%$, indicating that nitrogenfixing algae may have been an abundant source of organic matter Consistently high values of percent organic carbon and nitrogen indicate high levels of organic matter deposition and aquatic productivity in Zone 2. High aquatic productivity in GSL1 throughout Zone 2 is consistent with organic sediment observed above the gradational contact in GSL1 RC-1. $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values that increase throughout the zone may indicate continued evaporative enrichment within GSL1 that began at the gradational contact. Once again, conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ values proved inappropriate as low $\delta^{13} \mathrm{C}_{\text {org }}$ values in Zone 2 would suggest low productivity through this interval, contradicting interpretations from all other parameters.

Zone 3(~1577 AD to $\sim 1957$ AD)
In Zone 3, percent organic carbon ranged from $38.4 \%$ to $45.2 \%$ and was less variable than Zone 2. Values remained relatively constant throughout Zone 3. Percent nitrogen increased gradually from $2.6 \%$ to $3.2 \%$ with variability remaining similar to Zone 2 . $\delta^{13} \mathrm{C}_{\text {org }}$ values ranged from $-29.1 \%$ to $-28.1 \%$ and were less variable than values from Zone 2. $\delta^{13} \mathrm{C}_{\text {org }}$ values abruptly increased through the transition of Zone 2 and 3 (from $29.3 \%$ to $-28.9 \%$ ), and gradually increased throughout the remainder of the zone (from $28.9 \%_{0}$ to $-28.2 \%$ ). $\delta^{15} \mathrm{~N}$ values ranged from $-1.1 \%$ to $0.4 \%$ with variability similar to Zone 2. Values rapidly shifted at the base of Zone 3, increasing from $-0.7 \%$ to $0.4 \%$ in $\sim 31$ years. After the shift, $\delta^{15} \mathrm{~N}$ values decreased gradually throughout the remainder of
the zone from $0.4 \%$ to $-0.3 \%$. $\mathrm{C} / \mathrm{N}$ ratios gradually decreased from 16.8 to 13.7 and maintained variability similar to Zone $2 . \delta^{18} \mathrm{O}_{\mathrm{lw}}$ values are relatively constant ranging from - $18.7 \%$ to $-17.0 \%$.
$\mathrm{C} / \mathrm{N}$ ratios throughout Zone 3 had a similar range (13.7 to 16.8 ) as Zone 2 ( 13.3 to 16.0). This similar range of values indicates that the source of organic material deposited in GSLI had not likely changed from Zone 2 to 3 and that it remained autochthonous despite relatively high $\mathrm{C} / \mathrm{N}$ ratios. As well, throughout most of Zone $3, \delta^{15} \mathrm{~N}$ values ranged close to $0 \%$, indicating nitrogen-limiting conditions. Similar to Zone 2, nitrogenlimitation was likely the cause of elevated $\mathrm{C} / \mathrm{N}$ ratios in Zone 3. Additionally, consistently high percent organic carbon values and increasing percent nitrogen values suggest that high aquatic productivity and organic matter deposition continued from Zone 2 to 3 . High aquatic productivity and autochthonous deposition of organic material is consistent with visibly organic sediment observed through this interval of the GSL1 sediment profile. Additionally, the positive shift in $\delta^{15} \mathrm{~N}$ values at the onset of Zone 3 may indicate a brief change in nitrogen cycling within GSLI. Elevated $\delta^{15} \mathrm{~N}$ signatures at the bottom of Zone 3 may reflect a brief influx of nitrogen from outside the basin. $\delta{ }^{18} \mathrm{O}_{\mathrm{lw}}$ values are higher in Zone 3 than Zone 2, suggesting an increase in evaporative enrichment within GSL1. Similar to $\delta^{15} \mathrm{~N}, \delta^{13} \mathrm{C}_{\text {org }}$ values abruptly increased at the onset of Zone 3, a shift that is conventionally associated with increased aquatic productivity. However, there is a lack of evidence in any other parameter to support an abrupt increase in aquatic productivity, therefore it is unlikely that a conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ is appropriate for this zone

Zone 4 ( 1957 AD to $\sim 2007$ AD)
In Zone 4, percent organic carbon and nitrogen values gradually increased from $41.4 \%$ to $44.4 \%$ and $2.9 \%$ to $3.3 \%$, respectively. $\delta^{13} \mathrm{C}_{\text {org }}$ values decreased from $-29.5 \%$ to $-28.2 \%$. $\delta^{15} \mathrm{~N}$ values ranged from $-0.5 \%$ to $0.1 \%$ with a similar variability to Zone 3 and remained constant. $\mathrm{C} / \mathrm{N}$ ratios ranged from 13.4 to 14.6 and were among the lowest in the record. Variability remained the same as Zone 3 and values were relatively constant throughout the zone. $\delta{ }^{18} \mathrm{O}_{\mathrm{lw}}$ values in Zone 4 increased markedly from $-17.1 \%$ to $-10.1 \%$ and were the highest in the record.
$\mathrm{C} / \mathrm{N}$ ratios in Zone 4 (13.4 to 14.6) were among the lowest in the GSL1 record. These ratios were the closest in the record to ratios typically reported as aquatic in origin suggesting that the supply of organic material in Zone 4 was from an autochthonous source. As well, in Zone $4, \delta^{15} \mathrm{~N}$ values of around $0 \%$ suggest that nitrogen was limited. Nitrogen-limiting conditions are then likely the reason $\mathrm{C} / \mathrm{N}$ ratios in Zone 4 are slightly higher than those expected from autochthonous organic material. Zone 4 also represents the highest percent organic carbon and nitrogen values in the GSL1 record. These values indicate high aquatic productivity and deposition of organic material simılar to Zone 3. Percent organic carbon and nitrogen values in Zone 4 that are slightly higher than Zone 3 are likely the result of recently deposited sediment that has not yet undergone diagenesis. An autochthonous source of organic material and high aquatic productivity is consistent with visibly organic sediment at the top of the GSL1 sediment record. $\delta^{18} \mathrm{O}_{\mathrm{tw}}$ values that increase to the highest in the record may suggest that the highest degree of evaporative enrichment occurred in Zone 4. As well, the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ value of $-10.1 \%$ at the top of Zone 4 is typical of values found in the evaporation-dominated lakes of SRD (Brock et al.,
2007). Declining $\delta^{13} \mathrm{C}_{\text {org }}$ values are conventionally associated with declining aquatic productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). Such an interpretation would contradict all other parameters, suggesting that conventional interpretation is not appropriate for Zone 4. As well, diagenesis can cause an increase in $\delta^{13} \mathrm{C}_{\text {org }}$ values (Herczeg, 1988). Therefore, the sharp decrease in $\delta^{13} \mathrm{C}_{\text {org }}$ values near the top of Zone 4 may be the result of uppermost sediments not having undergone diagenesis.

## Chapter 5-Discussion

Constructing a millennial-scale hydrologic history for the Slave River system requires a systematic examination of data obtained from the stratigraphic records of SR 1, SD34 and GSL1. A change in depositional environment interpreted from a change in almost all parameters at the visible contact in each of the stratigraphic records will initially be discussed. This will help to determine the timing, and potential drivers of change at each study site. In addition, a variety of factors that have caused conventional interpretation of $\mathrm{C} / \mathrm{N}$ ratios to be contradictory to other measured parameters at each study site will be discussed. An open-drainage diatom indicator record for GSL1 is then explored to aid in the paleohydrological reconstruction and is compared to parameters measured for GSL1 withın this study. A second interval of hydrologic change not widely identified in the geochemical record of GSL1 is evident in the diatom record. This change appears to be captured in only the $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ and $\delta^{13} \mathrm{C}_{\text {org }}$ records, highlighting the sensitivity of these two records to hydrologic change that occurred at GSL1. Complications with conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ in GSL1 and SD34 are then addressed in order to establish a $\delta^{13} \mathrm{C}_{\text {org }}$ interpretation consistent with all other parameters. Lastly, interpretations of key parameters from each study lake are used in conjunction with published reconstructed climate and hydrologic records to detail a $\sim 1200$-year record of hydrologic variability within the Slave River system.

### 5.1. A Change in Depositional Environment at the Sediment Contacts of SR1, SD34 and GSL1

A prominent stratigraphic change occurs at the inorganic-organic sediment contact common to all study sites. At each site, the inorganic sediment occurred at the base of the record and more organic-rich sediment extended from the contact to the top of the record. Interpretation of the organic material source above and below the contacts within each study lake was complicated by factors affecting the $\mathrm{C} / \mathrm{N}$ ratio that differed among these lakes. The interpretation of $\mathrm{C} / \mathrm{N}$ ratios at SR1 was conventional. At SR1, ratios below the contact were higher than values typically produced by aquatic sources $(<10)$ (Figure 23), clearly suggesting that organic material below the contact was from an allochthonous source. $\mathrm{C} / \mathrm{N}$ values above the contact approach the range typically produced by aquatic sources (Figure 23) more so than the values below the contact, suggesting that organic material above the contact in SRI was autochthonous.

In contrast to SR1, C/N ratios below the contact in SD34 were among the lowest in the record (Figure 23). An abrupt change in all parameters (Figure 17) was interpreted to suggest that diagenesis had affected the geochemical parameters below $\sim 1980 \mathrm{AD}$, indicating that elevated ratios above the contact were likely attributed to nitrogen loss as a result of diagenesis. An increase in aquatic productivity indicated by percent organic matter content, percent organic carbon and percent organic nitrogen values indicated that organic material above the contact was likely from an autochthonous source, similar to SR1. Additionally, low percent organic matter content, percent organic carbon and percent organic nitrogen values coupled with mineral-rich sediment (Figure 17), suggested an allochthonous source of organic material below the contact despite comparatively low $\mathrm{C} / \mathrm{N}$ ratios.

Figure 23 C/N ratios for study lakes, SRI, SD34 and GSL1 Visible sediment contacts are marked by horizontal dashed lines (bottom and top of GSL1 gradational contact are marked with dashed lines) Cellulose-mferred lake water $\delta^{* *} O$ is also included for GSL1 with the range of Slave River $\delta^{\prime *} O$ as reported by Brock et al (2008) Identified as a vertical dashed lines

In the GSL1 record, C/N ratios below the contact were higher than those typically derived from aquatic sources (Figure 23), suggesting that organic material in this interval was allochthonous. Similar to SD34, C/N ratios above the contact in GSL1 remained high. However, $\delta^{15} \mathrm{~N}$ values close to zero above the contact (Figure 22) suggested nitrogen-limiting conditions that have been shown to elevate $\mathrm{C} / \mathrm{N}$ ratios (Meyers and Teranes, 2001). Therefore, elevated $\mathrm{C} / \mathrm{N}$ ratios due to nitrogen-limiting conditions coupled with high percent organic carbon and percent organic nitrogen values suggested
autochthonous organic mater deposition above the contact in GSL1, sımilar to SD34 and SR 1. The shift in organic material source observed at the contact of each study lake was accompanied by a change in sediment composition, likely indicating a change in depositional environment.

Allochthonous organic material below the visible contact corresponds with low percent organic carbon and percent organic nitrogen values in each study lake and because the source of organic material is from outside the study basins, these values reflect the allochthonous source of organic material Therefore, low percent organic carbon and organic nitrogen values below the visible contacts of each study lake indicate that any supply of in-lake, aquatic organic material to each study basin is diluted by the high inorganic content of the allochthonous source.

Geochemical analysis of freshly deposited Slave River flood sediment collected in 2005 reveals that Slave River sediment has low organic carbon and organic nitrogen contents and high $\mathrm{C} / \mathrm{N}$ ratios, not unlıke the values observed below the visible contacts of SR1, SD34 and GSL1 (Table 4). As well, laminations observed at the base of the GSL1 sediment profile likely represent sporadic pulses of sediment to the basin suggesting riverine influence below the contact. Laminations in the sediment of GSL1, geochemical and isotopic characteristics similar to Slave River sediment and close proximity to relict Slave River distributary channels (Figure 24) suggest that the Slave River is a likely source of allochthonous organic material deposition in the lower strata of SR1, SD34 and GSL1. Additionally, $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values measured from the Slave River and below the contact in GSL1 (Brock et al, 2008) are both low (Figure 23), likely reflecting water that has undergone minimal evaporative isotopic enrichment. However, $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values below the
contact of GSL1 ( $-24.1 \%$ to $-20.2 \%$ ) are noticeably lower than contemporary Slave River values ( $-17.7 \%$ to $-192 \%$ ) and may represent a Slave River $\delta^{18} \mathrm{O}$ signature that is more depleted than the present, possibly due to increased snowmelt runoff from headwater regions.

Table 4 Comparison of percent organic carbon, percent nitrogen and C/N ratos measured from recently deposited Slave River flood sediment (Brock et al , 2010) to values measured below the sediment contacts of SR1, SD3ł and GSL1

| Sample | \% $\mathrm{C}_{\text {org }}$ | \%N(SRI, <br> values corrected for <br> vor <br> morganic nitrogen $)$ | $\underset{(S R 1, \text { CD } 34, G S L 1}{\mathbf{C / N}}$ values corrected for morganic nitrogen) |
| :---: | :---: | :---: | :---: |
| Slave River | 10 | 006 | 159 |
| SR1 | 26-102 | 0.22-0.81 | 114-139 |
| SD34 | 30-96 | 030-130 | 120-126 |
| GSL1 | 15-19 | 006-019 | 136-191 |

GSL water proximal to the SRD is turbid due to sediment supplied by the Slave River (Rawson, 1950). As a result, suspended sediment in GSL would have a similar geochemical signature to that of the Slave River. Therefore, GSL is also a potential source of allochthonous organic material to SD34 and GSL1 as both lakes are similarly elevated from the present-day shore of the lake (Figure 7). Reconstructions of the delta front using radiocarbon ages of wood samples by Vanderburgh and Smith (1988) have indicated that at $\sim 1180$ years BP, the delta front was located northwest of both SD34 and GSL1 (Figure 24). This would suggest that the position of the delta front likely did not cause the current positions of SD34 and GSL1 to be inundated by GSL within the last $\sim 1200$ years.

Time intervals for sediment deposited below the contact (SD34: ~762 AD to $\sim 998$ $\mathrm{AD}, \mathrm{GSL1}: \sim 803 \mathrm{AD}$ to $\sim 1142 \mathrm{AD}$ ) for both SD34 and GSL1 correspond to extremely low lake levels reconstructed for Lake Athabasca upstream (Wolfe et al., 2008a). Lake Athabasca and GSL are both large natural reservoirs in the same river system that have been shown to respond similarly during wet and dry years in the observational record (Bennett, 1970), making it unlikely that GSL water levels were high enough $\sim 1000$ years ago to mundate the two study lakes. Relatively low lake levels in GSL coupled with a documented SRD front that was lakeward of the current positions of SD34 and GSL1 would suggest that GSL is likely not the source of inorganic sediment below the contacts.

Figure 24. Soil map of Slave River Delta and surrounding area (Canada Department of Agriculture, 1971). Study Sites GSL1 and SD34 are highlighted as well as relict river channels located to the north of GSL1. Approximate position of SRD front at $\sim 1180$ years BP is drawn as a dashed line (Vanderburgh and Smith, 1988).

The change in the source of organic matter above the contacts of SR1, SD34 and
GSL1 from allochthonous to autochthonous marks a change in the depositional
environment of each study lake Autochthonous deposition of organic material and high aquatic productivity (as indicated by percent organic carbon, percent organic nitrogen, $\delta^{13} \mathrm{C}_{\text {org }}$ and $\delta^{15} \mathrm{~N}$ ) indicate depositional conditions within SR1, SD34 and GSL1 that are lacustrine above the visible contact. As well, ${ }^{210} \mathrm{~Pb}$ background is reached at similar depths for all three study sites (SR1: 15.25 cm , SD34: 15.25 cm , GSLI: 12.25 cm ) indicating that sedimentation rates in the uppermost sediments are relatıvely consistent among study sites. These sedimentation rates (SR 1: $0.082 \mathrm{~cm} /$ year; SD34: $0.061 \mathrm{~cm} /$ year; GSL1: $0.083 \mathrm{~cm} /$ year) are similar to rates from lacustrine environments upstream in the PAD ( $0.069,0.056,0.069 \mathrm{~cm} /$ year for PAD 5, 9, Bustard Island North Pond, respectively; Wolfe et al., 2008a).

A change in depositional environment from fluvial to lacustrine occurs at the contact within each study lake. However, this transition does not appear to occur simultaneously at SR1, SD34 and GSL1. In the shorter record of SR 1, the sediment contact occurs at $\sim 1786$ AD and geochemical parameters shift at $\sim 1818$ AD. At SD34, the sediment contact is coupled with a change in geochemical parameters at $\sim 1000 \mathrm{AD}$, indicating a shift to lacustrine conditions at the onset of the last millennium, much earlier than SR1. The sediment record of GSL1 is similar in length to SD34, however, the timing of the sediment contact and geochemical changes appears to occur $\sim 144$ years later than SD34. The significance of the temporal offset of the contact between SD34 and GSL1 is difficult to evaluate as dates for both sediment records have been extrapolated based solely on the ${ }^{210} \mathrm{~Pb}$ stratigraphy and may be associated with uncertainties associated with modeling.

### 5.2 Diatom Record at GSL1

A diatom record was established for GSL1 to supplement the geochemical stratigraphy. Diatom counts were conducted on GSLI RC1 by Michelle Tai from the University of Waterloo Environmental Change Laboratory. Diatom algae are sensitive to changes in physical, chemical and biological conditions and microhabitat availability and have been shown to be useful biomonitors of hydrologic change (Hall et al. 2004). Upstream in the PAD, small benthic and epipsammic diatom Fragllaria taxa have been shown to dominate in turbid open-drainage lakes and under flood conditions (Hall et al., 2004), making these taxa a likely indicator of past open-drainage intervals at GSLI.

High percent abundance of Fragilaria construens $v$ venter below the gradational contact in GSL1 suggest open-dramage conditions consistent with the fluvial depositional environment interpreted from physical and geochemical data (Figure 25). As well, the shift to a lacustrine depositional environment above the contact is associated with low abundance of Fragilaria construens $v$ venter However, at $\sim 1550$ AD there is a reemergence of these open-drainage diatom indicators. The re-emergence of Fragilaria construens $v$ venter suggests a change in hydrological conditions at GSL1. Hydrological change at $\sim 1550 \mathrm{AD}$ is not evident in the sediment composition of GSL1 and a second interval of open-drainage conditions appears to be captured by only two geochemical parameters ( $\delta^{13} \mathrm{C}_{\text {org }}$ and $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ ) (Figure 25). Changes in the GSL1 $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ and $\delta^{13} \mathrm{C}_{\text {org }}$ records coincide with those in the diatom record (Figure 25). However, conventional interpretation of increased $\delta^{13} \mathrm{C}_{\text {org }}$ corresponding to increased aquatic productivity within GSL1 has been contradictory to other geochemical parameters thus far. Therefore, because the $\delta^{13} \mathrm{C}_{\text {org }}$ record appears to be one of two sensitive geochemical parameters
that capture a second interval of open-drainage conditions was suggested by the GSLI diatom record, further investigation is required to evaluate the factors that influence the carbon isotope signature of organic material in these sediments.

Figure 25 GSL1 open-drainage diatom indicator record, GSL1 $\delta^{3} C_{\text {org }}$ record and GSL1 cellulose-inferred lake water $\delta^{* 8} O$ record Shaded interval indicates interval of open-drainage conditions above the gradational contact at GSL1 captured by the three parameters

### 5.3 Establishing an Alternative Interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ at GSL1 and SD34

Correspondence of the diatom and $\delta^{13} \mathrm{C}_{\text {org }}$ records from GSL1 suggests that $\delta^{13} \mathrm{C}_{\text {org }}$ is a sensitive indicator of hydrologic change. However, conventional interpretation of lake sediment $\delta^{13} \mathrm{C}_{\text {org }}$ proved to be contradictory to all other measured parameters in the GSL1
record. Therefore, an alternative interpretation of $\delta^{13} \mathrm{C}_{\mathrm{org}}$ is required. In order to develop an alternative interpretation for $\delta^{13} \mathrm{C}_{\text {org }}$, factors influencing the carbon isotope signature of organic material in the sediment record from GSL1 were evaluated.
$\delta^{13} \mathrm{C}_{\text {org }}$ in lake sediment is primarily determined by the $\delta^{13} \mathrm{C}$ of the dissolved inorganic carbon source ( $\delta^{13} \mathrm{C}_{\text {DIC }}$ ). Processes controlling the $\delta^{13} \mathrm{C}_{\text {DIC }}$ include the source and supply of inorganic carbon (e.g., from catchment runoff), ${ }^{13} \mathrm{C}$-enrichment from preferential uptake of ${ }^{12} \mathrm{C}$ by phytoplankton during photosynthesis, isotopic exchange with atmospheric $\mathrm{CO}_{2}$, recycling of ${ }^{13} \mathrm{C}$-depleted $\mathrm{CO}_{2}$ from respiration/decay of water column and bottom sediment organic matter, and uptake of bicarbonate $\left(\mathrm{HCO}_{3}{ }^{-}(\mathrm{aq})\right.$ at elevated pH (Wolfe et al., 2000).

Recent studies in the upstream PAD by Light (2010) and Lyons (2010) provide a basis for interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ in lake sediment core records. Investigation of water chemistry in PAD lakes of varying hydrologic classifications (open-drainage, closeddrainage and restricted-drainage) by Lyons (2010) revealed that at the beginning of the open-water season (May), closed-drainage basins had much higher dissolved inorganic carbon (DIC) concentration than open- and restricted-drainage basins (Figure 26). Early season productivity, as indicated by chlorophyll $a$ values, was also greatest in the closeddrainage basins early in the open-water season (Figure 25). Lyons (2010) observed that in early spring, $\delta^{13} \mathrm{C}_{\text {phytoplankton }}$ of closed-drainage basins was lower than the open-drainage basins (Figure 26). This is opposite what might be anticipated, as higher productivity would be expected to cause an increase in the $\delta^{13} \mathrm{C}_{\text {phytoplanhton }}$ of closed-drainage basins within the PAD which are more productive than open-drainage basins (Hall et al., 2004). The lower $\delta^{13} \mathrm{C}_{\text {phytoplankton }}$ values in closed-basins was attributed to high DIC
concentrations allowing for high carbon isotope fractionation between the DIC and phytoplankton (Figure 26), as is typically observed when carbon is not limiting (Keeley and Sandquist 1992). The low $\delta^{13} \mathrm{C}_{\text {phytoplankton }}$ values of closed-drainage lakes observed in the early spring may translate to lower $\delta^{13} \mathrm{C}_{\text {org }}$ values in the sediment record of these lakes in comparison to sediments deposited in open-drainage lakes.

Figure 26 Spatial and temporal variability of a) concentration of chlorophyll a, b) carbon isotope composition of phytoplankton and c) concentration of DIC from four PAD lakes based on samples from the 2007 open-water season and the spring of 2008 The May values represent an average of the 2007 and 2008 data Drainage type is indicated by symbol type closed-drainage basins are solid, restricted-drainage basin is shaded, and open- drainage basin is an open symbol (from Lyons, 2010)

Insight into the controlling factors influencing carbon isotope dynamics in PAD lakes by Lyons (2010) has been used by Light (2010) to interpret a lake sediment $\delta^{13} \mathrm{C}_{\mathrm{org}}$ record from PADI, a closed-drainage lake. Multi-proxy paleolimnological analysis has revealed westward expansion of Lake Athabasca into the low lying interior of the PAD during the Little Ice Age (LIA), a period of increased summer discharge in the Peace-Athabasca
system (Wolfe et al., 2008a; Sinnatamby et al., 2010; Johnston et al., 2010). Light (2010) developed a $\sim 600$-year $\delta^{13} \mathrm{C}_{\text {org }}$ record for PAD 1 (Figure 27) which was situated at the margin of Lake Athabasca water levels during the LIA. $\delta^{13} \mathrm{C}_{\text {org }}$ values at the top and bottom of the PAD1 record were lower than those during the LIA ( $\sim 1600$ AD to $\sim 1900$ AD) (Figure 27). High $\delta^{13} \mathrm{C}_{\text {org }}$ values during the LIA correspond to a variety of parameters that suggest open-drainage conditions at PAD1 as a result of Lake Athabasca inundation (Johnston et al., 2010). This suggests that the early season $\delta^{13} \mathrm{C}_{\text {phytoplankton }}$ signature is captured in the lake sediment of PAD1 and that $\delta^{13} \mathrm{C}_{\text {org }}$ signatures during highly productive closed-drainage conditions within the PAD can be significantly lower than intervals of open-drainage conditions.

PAD1 and GSL1 are both closed-drainage basins and are hydrologically isolated from lake or river influence. These basins have noticeable similarities in their $\delta^{13} \mathrm{C}_{\text {org }}$ stratigraphic records. Both profiles are characterized by low $\delta^{13} \mathrm{C}_{\text {org }}$ values at the top of the record and high values during the LIA (Figure 27). The low values at the top of the GSL1 record correspond to closed-drainage conditions, similar to PAD1. Therefore, it appears that the early season $\delta^{13} \mathrm{C}_{\text {phytoplankton }}$ signature captured in the lake sediment of PAD1 is also captured in the sediment of GSL1. Interpreting high GSL1 $\delta^{13} \mathrm{C}_{\mathrm{org}}$ values to correspond with open-drainage conditions, is consistent with interpretation of fluvial, open-drainage conditions below the sediment contact and is also consistent with diatom and $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ records that suggest GSLI has experienced three hydrologic shifts in the past $\sim 1200$ years (Figure 27).

Figure 27 Comparison of $\delta^{13} C_{\text {org }}$ records from three closed-drainage basins a) PAD1 $\delta^{13} C_{\text {org }}$ record (from Light, 2010), b) GSL1 open-drainage diatom indicator record, c) GSL1 $\delta^{3} C_{\text {org }}$ record, d) GSL1 cellulose-mferred lake water $\delta^{88} O$ record and e) SD34 $\delta^{3} C_{\text {org }}$ record Shaded intervals indicate open-drainage conditions Dashed black lines indicate sediment contacts for GSL1 (gradational contact) and SD34 (abrupt contact)

SD34 is classified as a closed-drainage basin and is currently hydrologically similar to both GSL1 and PAD1. The SD34 $\delta^{13} \mathrm{C}_{\text {org }}$ profile shows some similarities to the $\delta^{13} \mathrm{C}_{\text {org }}$ profile profiles from GSL1 and PAD1 (Figure 27). Low $\delta^{13} \mathrm{C}_{\text {org }}$ values at the top of the SD34 record that correspond to closed-drainage conditions suggest that, similar to GSL1 and PAD 1 , the early season $\delta^{13} \mathrm{C}_{\text {phytoplanton }}$ signature is captured in the lake sediment. It is then likely that low $\delta^{13} \mathrm{C}_{\text {org }}$ values in the SD34 record correspond to closed-drainage conditions and high values correspond to open-drainage conditions. The interpretation of high $\delta^{13} \mathrm{C}_{\text {org }}$ values below the contact of SD34 is consistent with other geochemical parameters that suggest fluvial, open-drainage conditions. However, the $\delta^{13} \mathrm{C}_{\text {org }}$ record of SD34 suggests a second interval of change above the contact. New interpretation of the

SD34 $\delta^{13} \mathrm{C}_{\text {org }}$ record suggests a re-emergence of open-drainage conditions at $\sim 1300 \mathrm{AD}$ that is not captured by any other geochemical parameter in the SD34 record.

### 5.4 Paleohydrology of the Slave River and Great Slave Lake over the Past Millennium

New understanding of GSL1 and SD34 $\delta^{13} \mathrm{C}_{\text {org }}$ records contribute to developing a ~1200-year paleohydrologic reconstruction of the Slave River and GSL. The paleohydrology of the PAD, an upstream delta similar to the SRD that has been extensively studied will be used to compare with paleohydrologic interpretation downstream. Discussion of the paleohydrologic record of the Slave River and GSL is separated into five time intervals based on interpreted hydrologic change at the study basins and are discussed in chronological order: Early Medieval Period, Medieval Period, Late Medieval Period, Little Ice Age and Post Little Ice Age.

### 5.4.1 Early Medieval Period ( $\sim 750 \mathrm{AD}$ to $\sim 1150 \mathrm{AD}$ )

At the beginning of the last millennium, the climate at the headwaters of the PeaceAthabasca river system was characterized by warm winter temperatures and high growth season relative humidity of the MP (Edwards et al., 2008). The warm climate was coupled with a spring melt of annual snowpack that was too rapid to adequately sustain streamflow, which caused low summer discharge through the Peace-Athabasca river system (Edwards et al., 2008; Wolfe et al., 2008a). The rapid melt of the annual snowpack in the headwaters of the Peace-Athabasca river system caused a very large, but "flashy" spring freshet (Wolfe et al., 2008a). Because the Peace and Athabasca rivers are major tributaries of the Slave River, it is likely that a flashy freshet occurred downstream
as well. Additionally, research by Jarvis (2008) has identified the MP as a time of high ice-jam flood frequency in the PAD. Years of increased ice-jam flood frequency in the PAD have been shown to correspond to similar conditions downstream in the SRD (Mongeon, 2008; Brock et al., 2010). Therefore, it is likely that during the Early MP, ice-jam flood frequency at the SRD was also high. Frequent ice-jam flood events coupled with a large flashy spring freshet early in the last millennium could deliver river water, heavily laden with inorganic sediment to SRD lakes and could account for fluvial depositional environments below the contacts of SD34 and GSL1. $\delta^{13} \mathrm{C}_{\text {org }}$ values below the contact in SD34 ( $-25.9 \%$ to $-24.2 \%$ ) are similar to those measured from Slave River flood sediment ( $-24.6 \%$ ) by Brock et al. (2010), suggesting frequent Slave River flooding at SD34 Frequent Slave River flooding at GSL1 at the beginning of the last millennium is supported by laminations in the basal sediment as well as high abundances of opendrainage indicator diatoms. Additionally, $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values below the contact are low $(-24.0 \%$ to $-20.2 \%$ ) (Figure 28), likely reflecting water that has undergone minimal evaporative isotopic enrichment characteristic of an open-drainage basin. However, $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ values below the contact of GSL1 ( $-24.1 \%$ to $-20.2 \%$ ) that are noticeably lower than contemporary Slave River values ( $-17.7 \%$ to $-19.2 \%$ ) may represent a Slave River $\delta^{18} \mathrm{O}$ signature that is more depleted than the present, possibly due to increased snowmelt runoff from headwater regions.

Figure 28 Records of Slave River discharge (SD34 and SR1) compared to modeled North Saskatchewan River discharge (Model 1)(Case and MacDonald, 2003) and Great Slave Lake level record compared to Lake Athabasca lake level record (Bustard Island North Pond C/N ratios) (Wolfe et al, 2008a) SD34 Slave River discharge developed using $\delta^{3} C_{\text {urg }}$ values (vertical dashed line indicates the $\delta^{3} C_{m g}(-246 \%$ ) of 2005 Slave River flood sediment (Brock et al, 2010)), SRI Slave River discharge record developed using C/N ratios and GSLI Great Slave Lake level record developed using $\delta^{*} O_{l w,} \delta^{3} C_{m g,}$ values and open drainage diatom indicators Vel tical dashed lines within $\delta^{18} O_{11}$ record indicate $\delta^{* R} O$ values of the Slave River (-19 2\%), GSL (-179\%) and an average value for closed-dranage lakes in the SRD (-13 4\%) (Brock et al , 2007) Dark grey shaded intervals denote open-drainage condittons because of direct inundation of SD34 and GSL1 by the Slave River Light grey shaded intervalsfor SD34and GSLI denote open-drainage conditions caused by high GSL water levels during the LIA

### 5.4.2 Middle Medieval Period ( $\sim 1150$ AD to $\sim 1300 \mathrm{AD}$ )

Slave River influence on the hydrology of GSL1 and SD34, indicated by fluvial conditions depositing inorganic sediment, appears to end at the mineral-organic contact common to both sites. Isolation from Slave River flooding is characterized by a change in sediment composition from mineral-rich to organic-rich, accompanied by shifts in all geochemical parameters above the contacts of SD34 ( $\sim 1000 \mathrm{AD})$ and GSL 1 ( $\sim 1150 \mathrm{AD}$ to $\sim 1200 \mathrm{AD}$ ) and likely represents a shift to a lacustrine depositional environment.
$\delta^{13} \mathrm{C}_{\text {org }}$ in SD34 declines to values lower than Slave River sediment after $\sim 1000 \mathrm{AD}$ and GSL1 open-drainage diatom indicators decline after $\sim 1150 \mathrm{AD}$ suggesting a reduced influence of Slave River flooding on the two study sites above their respective contacts (Figure 28). Increased $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values at GSL1 above the contact indicate increased evaporation, further supporting a reduction in Slave River flood waters entering GSL1 above the contact. However, ice-jam flooding upstream in the PAD remains high until the end of the MP (Jarvis, 2008; Wolfe et al., 2008a), ~400 years later than reduced SRD icejam flood frequency suggested by the hydrologic isolation of SD34 and GSL1.

Chronological uncertainties within the SD34 and GSL1 sediment records could account for a temporal offset in the establishment of closed-drainage conditions between the SRD sites and the PAD. However, uncertainties in chronological modeling of GSL1 and SD34 are likely not large enough to account for a $\sim 400$ year offset. Geomorphologic setting of SD34 and GSL1 could account for the $\sim 400$ year offset, as the SRD sites may have had higher sill elevations than the PAD sites, making them less susceptible to river flooding. Additionally, shifts in distributary channel routing within the SRD may have contributed to the isolation of the basins during the Middle MP.

Reduced hydrological influence of the Slave River at the contacts of SD34 (~1000 $\mathrm{AD})$ and GSL $1(\sim 1150 \mathrm{AD}$ to $\sim 1200 \mathrm{AD})$, however, does occur during an interval ( $\sim 1000 \mathrm{AD}$ to $\sim 1300 \mathrm{AD}$ ) of low reconstructed North Saskatchewan River discharge inferred from tree-ring records (Case and MacDonald, 2003) (Figure 28). The North Saskatchewan River shares headwaters with the Peace-Athabasca-Slave river system, in the Columbia Icefields in the eastern Rocky Mountains. The Athabasca Glacier at the head of the Athabasca River is only $\sim 6 \mathrm{~km}$ from the Saskatchewan Glacier, a key headwater source for the North Saskatchewan River. Therefore, the discharge histories of these two river systems are likely to be similar.

Middle MP closed-drainage conditions at SD34 ( $\sim 1000 \mathrm{AD}$ to $\sim 1300 \mathrm{AD}$ ) parallels low North Saskatchewan River discharge as well as an interval of Rocky Mountain glacier expansion during the MP ( $\sim 1100 \mathrm{AD}$ to $\sim 1380 \mathrm{AD}$ ) outlined by Edwards et al. (2008) and the "Medieval Megadrought" ( $\sim 900 \mathrm{AD}$ to $\sim 1300 \mathrm{AD}$ ), a period of widespread hydrologic drought throughout western North America (Cook et al., 2004; Meko et al., 2007). Glacier expansion may have reduced inflow to glacier-sourced rivers such as the North Saskatchewan, Peace, Athabasca and Slave. Therefore, glacier expansion coupled with drought conditions within the Slave River basin, likely reduced Slave River discharge similar to the North Saskatchewan River and may have contributed to the establishment of closed-drainage conditions at SD34 and GSLI.

The emergence of closed-drainage conditions at SD34 ( $\sim 1000 \mathrm{AD}$ ) precedes similar closed-drainage conditions at GSL1 by $\sim 140$ years (Figure 28). The apparent delay in the isolation of GSLI could be the result of uncertainties within the extrapolation of both SD34 and GSL1 chronologies. However, the $\sim 140$-year offset may alternatively represent
a delay in GSL1 isolation from Slave River influence, possibly due to the hydrologic setting of GSL1 in the landscape. GSL1 is a relict river channel and may have been connected to the main drainage network of the Slave River during the early MP by a small channel active during high water periods. Evidence of other relict river channels that lead back to the Slave River can be observed a short distance north of GSL1 (Figure 24). Therefore, GSL1 may have been temporarily connected to these channels during frequent ice-jam flooding below the gradational sediment contact ( $\sim 800 \mathrm{AD}$ to $\sim 1150$ AD ), as is suggested by laminations and the $\delta^{13} \mathrm{C}_{\mathrm{org}}, \delta^{18} \mathrm{O}_{\mathrm{lw}}$ and open-drainage diatom indicator records. A channel connecting GSL1 to the main drainage network of the Slave River may account for the $\sim 140$ year delay in isolation of GSL1 compared to SD34, indicating that early MP ice-jam flooding was prolonged at GSL1 because its hydrogeomorphological setting was more susceptible to flooding than SD34. Additionally, the gradational contact of GSL1 ( $\sim 1150 \mathrm{AD}$ and $\sim 1200 \mathrm{AD}$ ) may also suggest that isolation of the basin occurred more gradually than at SD34, which had a much more abrupt sediment contact suggesting a sudden change in hydrological conditions.

### 5.4.3 Late Medieval Period ( $\sim 1300$ AD to $\sim 1550$ AD)

Closed-drainage conditions during the Middle MP at SD34 appear to end at $\sim 1300$ AD as $\delta^{13} \mathrm{C}_{\text {org }}$ values shift back to values similar to Slave River flood sediment (Figure 28). High $\delta^{13} \mathrm{C}_{\text {org }}$ values in the SD34 record indicate that a second period of opendrainage conditions occurred between $\sim 1300 \mathrm{AD} \sim 1918 \mathrm{AD}$. The change in the hydrology of SD34 at $\sim 1300 \mathrm{AD}$ suggested by the $\delta^{13} \mathrm{C}_{\text {org }}$ record corresponds to
increasing North Saskatchewan River discharge as indicated by the Case and MacDonald (2003) record (Figure 28) North Saskatchewan River discharge increased to some of the highest levels observed in the last millennium at the end of the $11^{\text {th }}$ century and remained high from the late MP-LIA transition to the end of the Little Ice Age (LIA) ( $\sim 1300 \mathrm{AD}$ to $\sim 1900 \mathrm{AD}$ ) (Figure 28). The increase in discharge at this horizon is likely in response to cooler climatic conditions during the transition from the Late MP to LIA, resulting in a more prolonged melt of the annual snowpack in the eastern Rocky Mountains (Case and MacDonald, 2003; Edwards et al., 2008). High North Saskatchewan River discharge coupled with the re-emergence of open-drainage conditions at SD34 suggests that Slave River discharge was high throughout the Late MP.

### 5.4.4 Little Ice Age ( $\sim 1550$ AD to $\sim 1860$ AD)

The SD34 $\delta^{13} \mathrm{C}_{\text {org }}$ record suggests that Slave River discharge becomes high during the Late MP and the sediment record of SR1 that spans $\sim 480$ years indicates that it remained high throughout the LIA. High $\mathrm{C} / \mathrm{N}$ values suggest allochthonous deposition of organic material at SR1 between $\sim 1550 \mathrm{AD}$ and $\sim 1860 \mathrm{AD}$, indicating a fluvial depositional environment (Figure 28). Since SR1 is located on an island in the Slave River upstream of the SRD and has no apparent inlets or outlets, it is expected that the basin would only receive Slave River flood water during a period of anomalously high discharge. Therefore, a fluvial depositional environment at SR1 between $\sim 1550 \mathrm{AD}$ and $\sim 1860$ AD suggests that during the LIA, Slave River discharge was considerably higher than present.

The onset of a second interval of open-drainage conditions at GSL1 during the LIA occurs $\sim 250$ years later than a similar re-emergence of open-drainage conditions at SD34. The shift to open-drainage conditions in GSL1 is indicated by high $\delta^{13} \mathrm{C}_{\text {org }}$ values between $\sim 1550 \mathrm{AD}$ and $\sim 1960 \mathrm{AD}$ that correspond to increased open-drainage diatom abundance and $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values ( $-17.8 \%$ to $-17.0 \%$ ) similar to that of GSL ( $-17.9 \%$ ) (Brock et al., 2007) (Figure 28). $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values similar to GSL and open-drainage conditıons indicated by $\delta^{13} \mathrm{C}_{\text {org }}$ and increased abundance of open-drainage diatoms appear to parallel increased Lake Athabasca water levels during the LIA (Wolfe at al., 2008a; Sinnatamby et al., 2010; Johnston et al., 2010) (Figure 28). Because Lake Athabasca and GSL are both large reservoirs within the same river system, it is likely that high LIA Lake Athabasca water levels would correspond to high LIA GSL water levels. Therefore, the re-emergence of open-drainage conditions during the LIA at GSL1 appears to represent inundation of GSL1 by GSL levels that are considerably higher than the present. This is the first evidence that GSL experienced a high-stand during the LIA, similar to that of Lake Athabasca and that the high-stand may have occupied the strandline visible in the landscape to the south of the SRD (Figure 3).

The approximate elevation range of GSL1 (between 161 masl and 163 masl) is between $\sim 3.6 \mathrm{~m}$ and $\sim 5.6 \mathrm{~m}$ above the highest gauged GSL water level ( $\sim 157.4$ masl) (Gibson et al., 2006a) (Figure 7), indicating that GSL water levels during the LIA would have to be at least $\sim 3.6 \mathrm{~m}$ higher than the present to inundate GSL1. GSL water levels $\sim 3.6 \mathrm{~m}$ greater than the present would be slightly larger than the average lake level change estimated for Lake Athabasca ( 2.3 m ) during the LIA (Johnston et al., 2010). An increase in GSL water levels by at least 3.6 m would not only have inundated GSL1, but
would have also inundated SD34 because the approximate elevation of SD34 ( $\sim 159$ masl) is lower than GSL1 (Figure 7). This would suggest that during the LIA, SD34 was inundated by GSL. It is likely that open-drainage conditions in SD34 at the transition from late MP to LIA were initially the result of high Slave River water levels inundating the lake and that during the LIA ( $\sim 1550 \mathrm{AD}$ to $\sim 1960 \mathrm{AD}$ ), elevated GSL lake levels began to inundate SD34. Additionally, the strandline observed in the landscape to the south of the SRD intersects GSL1 across its western end (Figure 3), suggesting that at present, it may have a similar elevation as GSL1. Therefore, the high-stand of GSL that inundated both GSL1 and SD34 during the LIA would likely have occupied the strandline as well.

The $\mathrm{C} / \mathrm{N}$ record of SRI indicates high water levels in the Slave River during the LIA. Because the water level of GSL is strongly influenced by riverine input and output (Gibson, 2006a), prolonged high Slave River discharge would expectedly raise lake levels. However, the large outlet at the mouth of the Mackenzie River results in water residence times that are relatively short for a lake the size of GSL (Gibson et al., 2006). These short residence times likely act to slow lake level rise in response to increased Slave River discharge. For GSL to inundate GSL1, Slave River input to the lake would likely have been high well before the onset of open-drainage conditions in GSL1 at $\sim 1550 \mathrm{AD}$. The $\delta^{13} \mathrm{C}_{\text {org }}$ record of SD34 suggests that Slave River discharge increased at $\sim 1300 \mathrm{AD}$ and remained high throughout the Late MP. Therefore, because GSL water level is closely linked to Slave River input it is likely that GSL water level began to rise at $\sim 1300 \mathrm{AD}$ and that $\sim 250$ years of high Slave River discharge elevated GSL water levels enough to inundate GSL1 throughout the LIA. In order to inundate GSLI, GSL
water levels would have to increase $\sim 3.6 \mathrm{~m}$ in $\sim 250$ years, at an average annual rate of $\sim 0.01 \mathrm{~m} /$ year. An increase of GSL water levels by $\sim 0.01 \mathrm{~m} /$ year is considerably less than typical GSL annual water level fluctuations ( 0.4 m ) (Gibson et al., 2006), suggesting that the estimated rate of lake level rise is plausible.

### 5.4.5 Post Little Ice Age (~1860 AD to $\sim 2007$ AD)

Interpretation of SR1, SD34 and GSL1 sediment records characterize the LIA as an interval of high discharge within the Slave River-GSL system. Alternatively, the sediment records of all three sites suggest that the transition from the LIA to the $20^{\text {th }}$ century is characterized by declining water levels. $\mathrm{C} / \mathrm{N}$ ratios similar to those expected from an autochthonous source suggest a shift in depositional environment at SRI from fluvial to lacustrine at the onset of the $20^{\text {th }}$ century (Figure 28). A lacustrine depositional environment at SR1 indicates isolation of the basin due to declining Slave River discharge. As well, declining $\delta^{13} \mathrm{C}_{\text {org }}$ values after $\sim 1918 \mathrm{AD}$ in SD34 suggest closeddrainage conditions as a result of reduced Slave River discharge and GSL water level (Figure 28). In the GSL1 record, declining $\delta^{13} \mathrm{C}_{\text {org }}$ values and open-drainage diatom indicator abundance (Figure 28) also suggest closed-drainage conditions early in the $20^{\text {th }}$ century, likely the result of lower GSL water levels. $20^{\text {th }}$ century GSL lake levels that are lower than the LIA are also indicated by GSL1 $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values ( $-15.1 \%$ to $-10.1 \%$ ) that diverge from values similar to GSL and become similar to present-day measurements from closed-drainage basins in the SRD (Figure 28) ( $-16.2 \%$ to $-10.6 \%$; Brock et al., 2007).

Declining Slave River discharge as indicated by multi-parameter paleolimnological analysis corresponds to similar declines in discharge reconstructed for the North Saskatchewan (Case and MacDonald, 2003), Peace and Athabasca rivers (Schindler and Donahue, 2006; Wolfe at al., 2008a) at the onset of the $20^{\text {th }}$ century. Reduced summer discharge through these river systems is thought to be the result of warmer $20^{\text {th }}$ century climate causing a flashy spring freshet that is significantly lower in magnitude than that observed during the MP (Wolfe et al., 2008a). A low-magnitude, flashy spring freshet coupled with low summer discharge in the Slave River at the onset of the $20^{\text {th }}$ century appears to have caused SR1 to become isolated from riverine influence. The $\delta^{13} \mathrm{C}_{\text {org }}$, $\delta^{18} \mathrm{O}_{1 \mathrm{w}}$ and open-drainage diatom records of GSL1 coupled with the $\delta^{13} \mathrm{C}_{\text {org }}$ record of SD34 indicate closed-basin conditions in the $20^{\text {th }}$ century (Figure 28). This indicates that GSL water levels have declined since the end of the LIA in response to reduced Slave River discharge, resulting in the hydrological isolation of GSL1 and SD34. Declining GSL levels throughout the $20^{\text {th }}$ century is consistent with declines in riverine input from the Slave River suggested by SR1 as well as declining Lake Athabasca water levels throughout the $20^{\text {th }}$ century as indicated by Wolfe et al. (2008a), Sinnatamby et al. (2010) and Johnston et al. (2010).

Analysis of lake sediment from SD34, GSL1 and SR1 suggests that water levels in the Slave River system have varied considerably over the past $\sim 1200$ years. Water levels declined throughout the $20^{\text {th }}$ century from millennial high levels reconstructed for the LIA. Low water levels throughout the $20^{\text {th }}$ century and the beginning of the $21^{\text {st }}$ century have resulted in closed-drainage conditions at the three study sites. In the past $\sim 1200$ years, closed-drainage conditions appear to occur only twice at SD34 and GSL1: from the
$20^{\text {th }}$ century to the present and during the MP. This suggests that currently, hydrological conditions within the Slave River system may have become similar to that of the Middle MP. However, high $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ values throughout the $20^{\text {th }}$ century at GSL1 that are unique within the record may suggest that hydrological conditions at this site are unprecedented over last $\sim 1200$ years.

## Chapter 6 - Conclusions

### 6.1 Summary

Multi-proxy analysis of lake sediment cores collected from SD34, GSL1 and SR1 provided a $\sim 1200$-year record of water level variation within the Slave River and Great Slave Lake. Sediment composition and elemental and stable isotope geochemistry proved to be sensitive indicators of hydrologic change for the three study basins. This study was also able to highlight complexities inherit in the interpretation of lake sediment records of $\mathrm{C} / \mathrm{N}$ ratios and $\delta^{13} \mathrm{C}_{\text {org }}$ values.

Interpretation of lake sediment $\mathrm{C} / \mathrm{N}$ ratios and $\delta^{13} \mathrm{C}_{\text {org }}$ values from SD34, GSL1 and SRI revealed that conventional, straightforward interpretation of these commonly applied paleolimnological measurements is not always appropriate. Conventional interpretation suggests that high $\mathrm{C} / \mathrm{N}$ ratios ( $>10$ ) correspond to an allochthonous source of organic material. However, interpretation of the high ratios above the contacts of SD34 and GSL1 using a conventional approach contradicted all other measured parameters. Interpretations from other geochemical parameters measured at the two study sites revealed that $\mathrm{C} / \mathrm{N}$ ratios of autochthonous organic matter were elevated due to nitrogen limitation at GSL1 and diagenesis at SD34. Conventional interpretation of $\delta^{13} \mathrm{C}_{\text {org }}$ suggests that high values correspond to high productivity (Schelske and Hodell, 1991; Hodell and Schelske, 1998; Meyers and Teranes, 2001). Interpreting the SR $1 \delta^{13} \mathrm{C}_{\text {org }}$ record in this way appeared appropriate, however similar interpretation of the SD34 and GSL1 $\delta^{13} \mathrm{C}_{\text {org }}$ records contradicted interpretations of all other measured parameters. $\delta^{13} \mathrm{C}_{\text {org }}$ records from SD34 and GSLI were both deemed sensitive records of hydrologic change only after new
understanding of sediment $\delta^{13} \mathrm{C}_{\text {org }}$ from upstream in the PAD provided a basis for nonconventional interpretation.

Interpretation of geochemical parameters such as $\mathrm{C} / \mathrm{N}$ ratios, $\delta^{18} \mathrm{O}_{\text {lw }}$ and $\delta^{13} \mathrm{C}_{\text {org }}$ in conjunction with sediment composition indicated riverine inundation of SD34 ( $\sim 760 \mathrm{AD}$ to $\sim 1000 \mathrm{AD}$ ) and GSL1 ( $\sim 800 \mathrm{AD} \sim 1200 \mathrm{AD}$ ) during the Early MP. River inundation of SD34 and GSL1 before the last millennium was attributed to Slave River discharge dominated by a large flashy spring freshet and high ice-jam flood frequency that delivered riverine sediment to the two study lakes. These hydrologic conditions are similar to that reconstructed for the upstream PAD and were likely caused by warm MP climate resulting in early, rapid melt of snowpack in headwater regions (Wolfe et al., 2008a; Jarvis, 2008).

A shift from a fluvial to lacustrine depositional environment at the contacts of SD34 ( $\sim 1000 \mathrm{AD}$ ) and GSL1 ( $\sim 150 \mathrm{AD}$ to $\sim 1200 \mathrm{AD}$ ) appeared to mark a shift to closeddrainage conditions early in the last millennium. Closed-drainage conditions at SD34 coincided with the "Medieval Megadrought" ( $\sim 900 \mathrm{AD}$ to $\sim 1300 \mathrm{AD}$ ), a period of widespread hydrologic drought throughout western North America (Cook et al., 2004; Meko et al., 2007) and corresponded to an interval of extremely low North Saskatchewan River discharge reconstructed by Case and MacDonald (2003). Drought conditions in western North America coupled with low North Saskatchewan River discharge likely correspond to low annual Slave River discharge from $\sim 1000 \mathrm{AD}$ to $\sim 1300 \mathrm{AD}$. Low Slave River discharge may have contributed to the onset of closed-drainage conditions by reducing the impact of ice-jam flood events at SD34 and GSL1. However, reduced icejam flood frequency indicated by closed-drainage conditions at SD34 and GSL1 precede
similar conditions in the PAD by $\sim 400$ years. Different geomorphic settings between SRD and PAD sites, shifts in the distributary channel network of the SRD and low Slave River discharge likely combined to account for the $\sim 400$ year offset and explain why SD34 and GSL1 became isolated during the MP when ice-jam flood frequency was high (Jarvis, 2008)

Low Slave River discharge appeared to end at $\sim 1300$ AD with a re-emergence of open-drainage conditions indicated by the SD34 $\delta^{13} \mathrm{C}_{\mathrm{org}}$ record. Open-drainage conditions were attributed to high Slave River discharge inundating SD34 throughout the Late MP. High Slave River discharge appeared to continue throughout the LIA as the SR1 sediment record identified high discharge from $\sim 1550 \mathrm{AD}$ to $\sim 1863 \mathrm{AD}$. These records indicate that Slave River discharge increased through the transition from Late MP to LIA and that discharge remained high throughout the LIA (Figure 29). Increased discharge was attributed to a delay in snowmelt generated runoff that sustained higher annual river discharge as a result of a shift to cooler climate conditions characteristic of the LIA (Wolfe et al., 2008a)

Cooler LIA climate and increased Slave River discharge appeared to cause high water levels in GSL during the LIA, similar to that observed upstream in Lake Athabasca (Sinnatamby et al., 2010, Johnston et al., 2010). Open-drainage diatom indicator abundance and $\delta^{13} \mathrm{C}_{\text {org }}$ records of GSLI indicated open-drainage conditions in GSL1 throughout the LIA and $\delta^{18} \mathrm{O}_{\mathrm{Iw}}$ values that were similar to GSL suggested that the opendrainage conditions were the result of GSL inundation. GSL inundation of GSL1 during the LIA further indicated that the GSL strandline visible to the landscape south of the SRD was likely been occupied during the LIA. Therefore, the SD34, SR1 and GSL1
sediment records indicated that GSL water levels began to rise at $\sim 1300 \mathrm{AD}$ as a result of elevated Slave River discharge at the transition from MP to LIA, reaching maximum levels during the LIA.

Figure 29. ~1200 year variation of Slave River discharge and multi-centennial change in Great Slave Lake water level. Schematic discharge profile is based on paleohydrologic records from SRD study sites GSL1, SD34 and SR1. Future discharge (dashed line) is based on expected discharge trends for upstream Peace and Athabasca rivers (Barnett et al , 2005; Wolfe et al., 2008a) Schematic water level profile is based on interpretation of GSL1 sediment record.

Millennial high water levels within the Slave River system during the LIA declined at the beginning of the $20^{\text {th }}$ century (Figure 29). A decline in Slave River discharge at the onset of the $20^{\text {th }}$ century appears to be captured in the SR1 and SD34 sediment records as a re-establishment of closed-drainage conditions. A decline in discharge through the Slave River system at the end of the LIA is further supported by $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ and $\delta^{13} \mathrm{C}_{\text {org }}$
records of GSL1 that suggest isolation of the basin from GSL likely due to $20^{\text {th }}$ century declines in GSL lake level (Figure 29).
$20^{\text {th }}$ century decline in discharge parallels a shift to a warmer climate regime that has been shown to cause an earlier, more rapid melt of the spring snowpack in the headwaters of the Peace and Athabasca rivers (Wolfe et al., 2008a). The sediment records of the three study lakes indicated that water levels within the Slave River system have declined from the high levels that characterized the LIA, falling to levels potentially similar to the Middle MP. However, high $\delta^{18} \mathrm{O}_{\mathrm{lw}}$ values throughout the $20^{\text {th }}$ century at GSL1 that are unique within the $\sim 1200$ record may suggest that hydrological conditions at this site are unprecedented in the last $\sim 1200$ years.

These findings are able to establish a link between hydrologic conditions within the Slave River system and those upstream in the PAD and Lake Athabasca. Sediment records from SD34, GSL1 and SR1 demonstrated that in response to shifting climate regimes, the hydrology of the Slave River system responded broadly similar to the PAD. This indicates that hydrologic change upstream in the headwaters of the Slave River has historically translated downstream to the SRD and GSL. River discharge in the PeaceAthabasca river system is expected to continue to decline throughout the $21^{\text {st }}$ century as a result of reduced glacier extent and snow pack depth in its headwater regions (Wolfe et al., 2008a). Therefore, Slave River discharge and GSL water levels that have declined over the last $\sim 200$ years are also likely to continue declining throughout the next century, possibly reaching levels unprecedented in the last $\sim 1200$ years, if such levels have not already been reached.

### 6.2 Management Implications

This study has established a $\sim 1200$-year paleohydrologic record for the Slave River and GSL. It has shown the interconnectedness in the hydrology of the SRD and PAD and has been able to demonstrate how the Slave River system responds to changes in climate. Although climate and water levels in the Slave River system appear to have returned to those similar to the Middle MP (increasing winter temperatures, growth season relative humidity, flashy spring freshet and lower discharge), it is likely that the flashy freshet will be considerably smaller than earlier in the millennium (Wolfe et al., 2008a). Snowpack depth and alpine glaciers in Peace-Athabasca-Slave river headwater regions that have historically contributed to annual flow have been shown to be in decline (Barnett et al., 2005; Lapp et al., 2005; Rood et al., 2005). A decline in source water entering the Peace-Athabasca-Slave system that is expected to continue would suggest that water levels may be heading toward unprecedented low levels in the context of the last millennium.

Declining streamflow will likely amplify current challenges in the management of water within Peace-Athabasca-Slave system as various stakeholders depend on this water resource. As the water available for stakeholder use declines, balancing the natural environment, water supply for hydroelectric facilities and consumptive use by humans will be a major challenge for future management of this river system. Of principle concern is the Athabasca Tar Sands development, which continues to expand, removing water from the Athabasca River for use in oil extraction. If declining streamflow in the Peace-Athabasca-Slave system is not managed carefully in the future, it may lead to unprecedented water shortages throughout the basin.

### 6.3 Future Recommendations

The $\sim 1200$-year hydrologic record for the Slave River system could be strengthened in a variety of ways. Interpretation of $\mathrm{C} / \mathrm{N}$ ratios from GSL1 attributed elevated ratios to nitrogen limitation and pigment analysis of GSL1 sediment could be used to test this hypothesis. Additionally, establishing a diatom record for SD34 would supplement geochemical parameters and may possibly strengthen $\operatorname{SD} 34 \delta^{13} \mathrm{C}_{\text {org }}$ interpretation.

Because GSL1 appears to lie at the margin of the LIA GSL high-stand, the GSL1 water level record only represents maximum GSL levels. Sampling several other lakes south of GSL1 that are closer to the GSL shoreline would provide insight into the timing, rate and extent of GSL expansion during the LIA. As well, locating a study site on GSL similar to the Bustard Island North Pond on Lake Athabasca (Wolfe et al., 2008a; Johnston et al., 2010) would most likely provide a more detailed long-term record of GSL water level change. The record of GSL water level established in this thesis is based on high-water intervals, thus a record that captures low-water intervals (such as the Bustard Island North Pond record) would improve understanding of long-term GSL hydrology.

## SD34

## Chronology

Background 210Pb @15 25 cm
(Average value $1525-3725 \mathrm{~cm}$ ): $1.895 \mathrm{dpm} / \mathrm{g}$
Cum. Dry mass Regression Line:

| Slope | -0.019 |
| :--- | ---: |
| y- <br> inter | 38.272 |

*dates are extrapolated below $1375-\mathrm{cm}$ depth using linear reg of cumulative dry mass and CRS dates (extrap date=cum dry mass-b/m)
** dates are extrapolated below $3725-\mathrm{cm}$ depth using linear reg of depth and CRS dates from $0-3725 \mathrm{~cm}$

Unsupported Pb-210 (CRS Model):
