Abstract

The genomes of the first two discovered magnetotactic bacteria (MTB) belonging to the *Gammaproteobacteria*, strains BW-2 and SS-5¹, were sequenced, sealed, annotated and compared to MTB of other phylogenetic groups. Cells of both strains are rod-shaped and biomineralize cuboctahedral and elongated octahedral crystals of magnetite, respectively, that are enveloped in a protein-embedded, lipid-bilayer membrane referred to as the magnetosome membrane or vesicle. The crystals and their associated membranes are known as magnetosomes. Magnetosome crystals consist of either magnetite (Fe₃O₄) or greigite (Fe₃S₄) and, because of their specific mineral compositions, crystal morphologies and sizes, the biomineralization processes involved in magnetosome formation are thought to be under strict genetic and (bio)chemical control through the action of the proteins associated with the magnetosome membrane. These biomineralization proteins are referred to as the Mam and Mms proteins, and the genes encoding them, the *mam* or *mms* genes. Known species of MTB phylogenetically belong to the *Alpha-*, *Gamma-*, and *Deltaproteobacteria* subgroups of the *Proteobacteria* phylum, the *Nitrospira* phylum and the candidate phyla *Latescibacteria* (WS3) and *Omnitrophica* (OP3). Complete or partial genomes sequences are available for MTB of most of these phylogenetic groups. A notable exception is genomic sequences from MTB from the *Gammaproteobacteria*.

The focus of this doctoral dissertation is the presentation of the first complete genome sequences of gammaproteobacterial MTB as well as a comparison of the genomes and, in particular, a comparison of the magnetosome genes of MTB of other phylogenetic groups. Specific goals were to determine the origin and evolution of the magnetosome genes as well as to determine the metabolic potential of these MTB strains.

The genomes of strains BW-2 and SS-5 are 4,103,727 bp and 3,729,439 bp in size, respectively, containing 3,838 and 3,724 coding sequences, respectively. Magnetosome genes form a single cluster about 32,781 kb in length in the genome of strain BW-2, while magnetosome genes make up two clusters in the strain SS-5 genome, of about 29,446 and 5,034 kb in length. Interspersed among the magnetosome genes of both MTB strains are unique coding sequences that share high homology to uncharacterized, hypothetical magnetosome-associated genes of other MTB. As to general metabolism, the genomes of both MTB strains contain the genes necessary for the utilization of the Calvin-Benson-Bassham cycle for autotrophy as well as the genes necessary for the oxidation of reduced sulfur compounds as a source of electrons. This is consistent with their ability to grow as microaerophilic chemolithoautotrophs using thiosulfate and sulfide as electron donors. Finally, numerous sets of genes are present in both genomes that explain other important and minor metabolic features of the strains.

In this work genes common to octahedral magnetite producers across phylogenetic groups are identified as well as potential uncharacterized magnetosome genes and the mode of acquisition and molecular evolution of the phenotype across phylogenies will be assessed.

Chapter 1 Introduction

Discovery and general features of magnetotactic bacteria

Magnetotactic bacteria (MTB) are a phylogenetically diverse group of Gram-negative, aquatic, motile prokaryotes that, although are metabolically and morphologically heterogeneous, share in common the ability to biomineralize intracellular, membrane-bounded, magnetic nanocrystals of magnetite (Fe_3O_4) and greigite (Fe_3S_4).²⁻⁶ These magnetic nanocrystals crystals, together with the membrane they are formed within, are referred to as magnetosomes⁷ and impart a permanent magnetic dipole moment to the cell. In turn, this magnetic dipole moment causes cells of MTB to align passively along the Earth's geomagnetic field lines, similarly to a compass needle, while they swim.^{2,4,6,8-13} The combination of this passive magnetic orientation and active motility is referred to as magnetotaxis, the defining feature of MTB.^{10,13}

Magnetotaxis was first observed by the Italian microbiologist Salvatore Bellini which he then described in 1963 in the University of Pavia publication *Istituto di Microbiologia*.¹⁴ While observing a sample of mud and water, he noticed a large subset of cells swimming consistently in a northward direction. Referring to them as “batteri magnetosensibili,” or magnetosensitive bacteria, he hypothesized that the magnetically influenced behavior was due to the presence of an internal “magnetic compass.” This was confirmed in 1974 when Richard P. Blakemore independently rediscovered MTB and observed magnetosomes for the first time as described in his seminal paper on the topic.^{6,12,15}

Ecology of MTB

MTB are ubiquitous in freshwater, brackish marine and hypersaline sedimentary habitats and water columns that are chemically stratified,¹⁶ and have even been found in relatively moist soils.¹⁷ Despite their cosmopolitan distribution, as generally microaerophilic gradient organisms^{4,12} they are exquisitely sensitive to concentrations of O₂ and other compounds^{12,18} that occur in vertical concentration gradients in natural habitats. In chemically-stratified habitats MTB occur in their highest numbers at the oxic-anoxic interface (OAI) or what has also been referred to as the oxic-anoxic transition zone (OATZ).^{6,9,10,12,13,19–21} This is the microaerobic zone that lies between the oxic and the anoxic zones that is typified by a very low concentration of O₂ but overlaps with many reduced compounds some of which are used as electron donors for bacterial growth.^{6,9,10,12,13,19–21} These reduced compounds include reduced sulfur species such as sulfide (S²⁻).^{3,4,12,13,21–28} A number of MTB have now been discovered below the OAI in the anoxic zone which is devoid of O₂.^{12,13,29,30} In general, most magnetite-producing MTB are found at the OAI proper^{4,12,26,29–34} while greigite-producing and some magnetite-producing species are present below the OAI in the anoxic zone^{4,12,13,16,26,31,35} which is also often sulfidic.^{4,6,35–37} This information suggests that MTB would thus likely be microaerophiles or anaerobes or both and the subsequent isolation and cultivation of many MTB confirms this supposition.^{9,10,38–42} Although MTB, as a group, are very sensitive to atmospheric concentrations of O₂ (it is toxic to them) and tend to occupy niches at mesophilic temperatures and at near neutral pH^{12,19,43,44}, some strains are able to exploit extreme habitats

including those that are highly alkaline,^{45,46} acidic,⁴⁷ hypersaline,^{48–50} or have high temperatures (up to 63°C)^{6,51} (e.g., hot springs) and low temperatures (e.g., the Antarctic)^{52,53}.

Function of magnetosomes and magnetotaxis

As described in the previous section, MTB are generally found in their highest numbers at the OAI.^{10,12,54} For many species, this is important for their survival and growth as it is the only location where their electron donors (e.g., reduced sulfur species such as S^{2-}) and acceptors (O_2) overlap in many environments.^{12,13} In addition, atmospheric concentrations of O_2 are toxic to these microaerophilic/anaerobic microorganisms,^{2,12,16,37,41,55} and thus MTB must efficiently locate and maintain this optimal position.^{11,13,38,56} The magnetosome mediated alignment along the Earth's geomagnetic field lines, coupled with chemotaxis, function to help the cell to more efficiently find their optimal O_2 concentration in a vertical concentration gradient systems.^{4,6,9,11,36} The magnetic polar directionality of the geomagnetic field is positioned at an angle relative to the surface of the earth. The angle of the magnetic field lines vary across the globe from pole to pole. This angle of dip is the vector that results from the combined horizontal and vertical aspects of the magnetic field as it angles vertically away from the earth and horizontally arcing from the direction of one pole to the other as illustrated in Figure 1.^{25,57} The field is horizontal at the magnetic equator (0°) and inclines more steeply closer to the magnetic poles such that it reaches a 90° inclination at magnetic north and south.^{25,57,58} In both hemispheres, it is thought that MTB swim downward along the geomagnetic field lines by rotating their flagella counterclockwise and reverse their direction by

rotating their flagella clockwise.^{13,25,59,60} MTB in opposite hemispheres have opposing polarities, or a predominant or preferred swimming direction under oxic conditions⁶¹ such that in the northern hemisphere most are north-seeking and those in the southern hemisphere are mostly south-seeking.¹⁶ North-seeking (swimming towards a south pole) in the northern hemisphere is also down-seeking and vice versa in the southern hemisphere. Thus, once aligned along the inclined Earth's geomagnetic field lines, north-seeking MTB, under oxic conditions, swim downwards along the chemogradient in response to it to the OAI. They then need only reverse their swimming direction under anoxic conditions by reversing their flagellar rotation enabling them to again find the OAI more readily.¹⁶ At the magnetic equator there are both north- and south-seeking MTB in equal amounts.^{10,13,25,55}

Figure 1 Illustrations of the Earth's Geomagnetic Field Lines

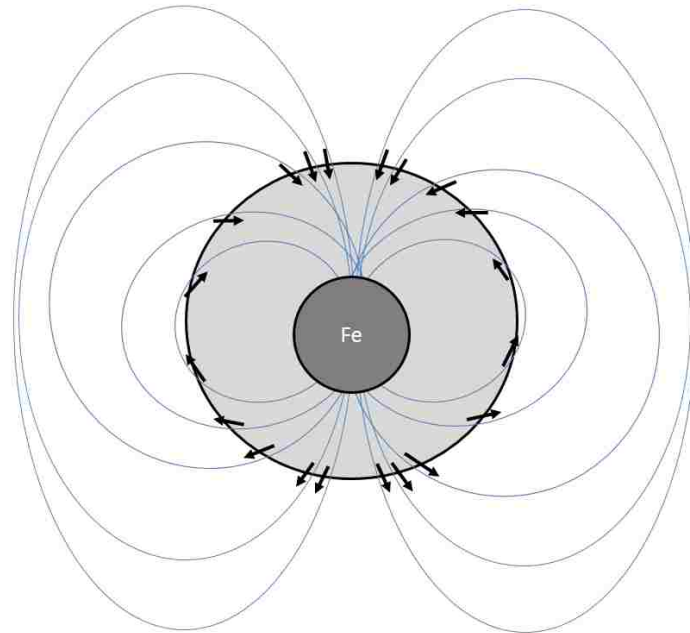

Diagram illustrating how magnetic field lines angle through the Earth's surface at different latitudes. Arrows indicate northward directionality of the geomagnetic field, blue lines represent magnetic field.

Once an MTB has passively aligned along the Earth's inclined geomagnetic field lines, it simply swims forward or in reverse, translating to up and down. This facilitates their movement in the water column or sediment along the opposing concentration gradients of O_2 decreasing from the surface with depth as reduced sulfur compounds increase in concentration. In doing so, the combination of magnetic field alignment and chemotaxis reduces a three dimensional search through the sediments, where the OAI is typically located, to one of a single dimension where cells swim forward and reverse (upward or downward) along the chemogradient, thereby conferring a selective advantage to the magnetotactic phenotype. ^{9,16}

Enrichment and separation of MTB for study

MTB generally are relatively easily enriched for in collected samples of mud and water by simply storing samples of collected sediment and water at room temperature in dim light.^{27,62} The MTB in a sample can be concentrated and collected by first allowing the sample to settle with a magnet placed on the outside of the sample container at the approximate location of subsequent OAI formation as depicted in Figure 2, a process called magnetic enrichment.

Figure 2 Magnetic Enrichment of MTB from a Sample of Water and Sediment

Magnetic enrichment of MTB from an environmental sample of water and sediment using a magnetic stir bar placed near the OAI. Over time MTB aggregate near the magnet as indicated by the arrow. (Figure adapted from Bazylinski 2013)

After several hours, a drop is extracted from this location from the inside of the container and examined by employing the hanging drop technique.¹² When using this technique a drop is placed on a cover slip which is inverted and placed on an O-ring affixed to a microscope slide

such that the sample drop hangs from the cover slip as depicted in Figure 3. When a magnetic field is imposed by the placement of the south pole end of a magnet at one side of the drop and the north pole end of another magnet at the other end of the drop, any MTB present can be microscopically observed aggregating at the edge of the drop nearest the magnet pole corresponding to the geomagnetic field pole affinity of the strains present.

Figure 3 Illustration of the Hanging Drop Technique

A drop of water and/or sediment from a magnetically-enriched environmental sample is placed on a cover slip and inverted on a rubber O ring affixed to a microscope slide. Arrow indicates the position geographically north seeking MTB will migrate to when the south pole of a magnet is placed at the position indicated by the S. (Figure adapted from Bazylinski 2013)

Collection and separation of MTB from non-magnetotactic bacteria in samples for various studies and experiments are achieved by exploitation of their magnetotactic behavior. The most commonly used method for this is through the use of the so-called capillary “magnetic racetrack,” as depicted in Figure 4.^{40,63} The racetrack is constructed by flame sealing the tapered end of a Pasteur pipette and inserting a cotton plug into the wide end, wedging it in at the site of taper. After sterilization of the racetrack, the sealed end is aseptically filled with filter-sterilized water past the cotton plug with a long syringe needle before addition of

the water and mud containing MTB to the wide end. To collect north-seeking MTB (i.e., generally those in the northern hemisphere), a magnetic field is then imposed on the racetrack by positioning magnets at either end with the south pole of the magnet facing the sealed end of the racetrack, and the north pole facing the wide opening of the race track. North seeking MTB are directed to the south poles of magnets because the Earth's geographical north pole is in fact, a south pole magnet.

Figure 4 Magnetic Racetrack

Pasteur pipette fashioned into a magnetic race track by heat sealing the tapered end, inserting a cotton plug at the taper, then autoclaving. Magnets are arranged at either end to set up a magnetic field after aseptically injecting sterile water or culture medium into the sealed end and environmental sample in the wide end. Small arrows point to location of contents, the long arrow indicates the direction of MTB motility. (Figure adapted from Bazylinski 2013)

In the case of south-seeking MTB the magnetic field would be reversed, as south seeking MTB are directed to the north poles of magnets because the Earth's south pole, is actually a north pole magnet. When high numbers of MTB are present in the original sample, they can be visualized accumulating at the sealed end using a dissecting microscope. As soon as sufficient

cells are collected, the end of the capillary is broken off and the cells removed with a sterile syringe. This technique works very well with fast swimming species (e.g., magnetococci), but for MTB that swim relatively slowly, the longer time allowed for migration increases the likelihood of contamination by non-magnetotactic bacteria in the racetrack.⁴⁰ MTB purified using this technique can be used in electron microscope studies, for DNA isolation or as inocula in growth experiments

Isolation in pure culture and cultivation

As MTB are generally very fastidious, they require specialized culture conditions for growth. It is often necessary to formulate custom O₂ concentration gradient semisolid medium based on the chemical conditions present in the sample where the particular MTB was found.^{40,64} Once the medium has been prepared it is then dispensed into screw capped test tubes to simulate an aquatic gradient column. The O₂ concentration gradient is achieved by the addition of O₂ scavenging reducing agents such as cysteine. Thiosulfate or sulfide are often added as well, which also serve dual purposes as reducing agents as well as electron donors depending on the suspected metabolism of the cells targeted for enrichment. Once the medium is dispensed and the tube capped, the trapped O₂ in the headspace diffuses into the medium from the surface. The result is the production of a stable O₂ concentration and redox gradient in the tube with a concomitant establishment of an OAI. The OAI can be visualized by the

addition of resazurin to the growth medium which is pink in the presence of O_2 but in its absence is colorless or light brown (the latter in the presence of some reduced sulfur species).

(Figure 5)

Figure 5 Visualization Representation of the Oxidic/Anoxic Interface (OAI) in Semisolid O_2 Concentration Growth Medium When Resazurin is Present

Tubes of semisolid O_2 concentration growth medium for the culture of strain BW-2. The OAI and band of cells are indicated by the arrow. The medium above the OAI is oxidic due to the presence of O_2 which can be discerned by the pink color, while the medium below the OAI is anoxic due to the absence of O_2 which is discerned by the absence of the pink color. The downward arrow indicates the direction of O_2 diffusion.

Once the OAI has been established and is visible, cells collected from the magnetic racetrack can be inoculated just below the OAI. Given the extremely fastidious nature of MTB, the major challenge is deducing a medium formulation that actually results in the growth of the isolated MTB.¹² In most cases MTB isolated from environmental samples do not survive or grow. In cases where the strain grows in culture, occasionally it grows only to a low cell density that

presents a challenge when conducting characterization experiments or acquiring significant amounts of DNA for cloning and sequencing.

Magnetosomes

Magnetosomes produced by MTB are defined as magnetic nanocrystals enveloped by a phospholipid-bilayer membrane.^{10,16,35,58} This membrane has been referred to as the magnetosome membrane and the magnetosome membrane vesicle^{10,13,25,65} and is the location of the nucleation and growth of the mineral crystal.^{4,30,35} It contains or is associated with a number of proteins not found elsewhere in the cell and thought to be responsible for the biomineralization and organization of magnetosomes in the cell.^{12,13,16,66,67} The composition, size and morphology of the magnetosome mineral crystals appears to be under strict genetic and (bio)chemical control which will be further discussed later.^{12,16,35} In addition, there is an important correlation between magnetosome crystal composition and morphology and phylogenetic affiliation in MTB that is discussed later.

Composition of magnetosome crystals

As previously stated, magnetosome crystals are composed of either the iron oxide magnetite (Fe_3O_4) or the iron sulfide greigite (Fe_3S_4). Generally a specific MTB will produce only one type of crystal although it has now been shown that some MTB produce both.⁵⁰

Greigite-producing MTB have been shown to also contain some non-magnetic precursors to magnetite including^{13,68} mackinawite (tetragonal FeS) and a sphalerite-type cubic FeS which have been observed to convert to magnetic greigite.⁶⁹ Interestingly, these precursor crystals are formed in a chain within the cell prior to them becoming magnetic.^{12,13,68} The S structural arrangement remains unchanged during the transformation while only the Fe atoms rearrange in a step wise process from cubic FeS to mackinawite to finally form magnetic greigite.^{68,69}

Figure 6 Conversion of the Putative Iron Sulfide Precursors of Greigite to Greigite in MTB

The putative stepwise chemical conversion of cubic FeS to mackinawite FeS to greigite in MTB. Light circles represent S atoms, dark circles represent Fe atoms, which rearrange around the S atom matrix in steps as FeS transforms incrementally to greigite. (Figure from Posfai 2006)

Magnetosome crystal size

Magnetosome crystals, regardless of whether they are composed of magnetite or greigite, fall within a narrow size range of between about 35 and 120 nm.² In this size range, crystals of both minerals have all of their atoms arranged such that their magnetic directionality is aligned in the same direction.^{70,71} Magnetic material arranged in this way is referred to as a single magnetic domain. In excess of this size range, the crystal becomes unstable and its magnetic material may spontaneously repartition, dividing into a multi-domain magnet with smaller domains that will be within the stable size range, but may be oriented in different directions thereby reducing the net magnetic directionality of the whole. Crystals smaller than

the optimal size range of 35 to 120 nm are superparamagnetic, meaning that at ambient temperature they can spontaneously change magnetic directionality.^{2,10,15,28,72} This is because there aren't enough atoms to influence one another to remain aligned and overcome the rearranging movement induced by thermal energy.^{70,71} The amount of force a magnetic material can produce is defined as its dipole moment. Single magnetic domain crystals of magnetite and greigite have the maximum amount of iron atoms that can all remain aligned, they have the maximum magnetic dipole moment per mass.^{2,35}

Magnetosome Crystal Morphology

Although some minor morphological variations have been observed within the same species under different growth conditions,¹¹ different strains of magnetite producing MTB produce different strain-specific magnetosome crystal morphologies that will be further discussed later. These crystal morphologies include cuboctahedral, bullet-shaped and elongated prismatic (Figure 7).^{3,10,13,28,30,55}

Greigite magnetosome crystal formation appears to be less tightly controlled generally resulting in crystals that have irregularly shaped surfaces devoid of clear facets, that is, subhedral.^{3,4,11,30,35} Even confirmed greigite crystals that generally lack clear facets, may have morphologies that are still species specific with respect to crystal size and dimension and that they are subhedral. For example, one strain might produce only equidimensional crystals of a certain size whereas another, only elongated crystals or yet another only bullet-shaped.³⁰ However there isn't yet a clear consensus as to whether all greigite magnetosome crystals are

species specific or whether they are just predictably subhedral.^{30,69} Cuboctahedral and elongated prismatic greigite crystals have been observed in uncultured MTB from environmental samples taken from salt marshes in the Woods Hole, MA area.^{69,73}

Figure 7 Magnetosome Crystal Morphologies in Cells of Different MTB

Transmission electron micrograph images of different magnetosome crystal morphologies. (b) Bullet- or tooth-shaped magnetite crystals (c), cuboctahedral magnetite crystals (d), elongated prismatic magnetite crystals (e) and irregularly-shaped greigite crystals. (Image modified from Lefevre 2011)

Magnetosome arrangement

Most MTB organize their magnetosomes via cytoskeletal elements into one or more relatively linear chains that align along the long axis of the cell, orienting their magnetic crystals end to end.^{11,25,54,74,75} The resulting effect is that the magnetic fields of each overlap and join additively to combine the individual magnetic moments of each crystal into one larger magnetic

moment. What is gained is in effect a larger stable magnet than the cell could biomineralize otherwise, as can be seen by imaging the way the resulting magnetic field bends the electron beam during transmission electron microscopy^{16,76,77} (Figure 8). Because the chains are fixed parallel to one another and to the cell, the torque applied by the geomagnetic field to the crystals is transferred to the cell, aligning it along geomagnetic north and south.

In light of the observations that the crystals at the peripheral ends of the magnetosome chains tend to be smaller than crystals more centrally located, it appears likely that they form at the ends of the chains.^{16,78} Usually greigite crystal magnetosomes are less strictly controlled in their orientation than magnetite magnetosomes and are often found to be arranged in somewhat disordered chains, although still eliciting the effect of a single magnet.^{2,4,30} Some magnetic cocci have also been found to form their magnetosomes in dispersed clusters, usually at the end of the cell corresponding to flagellar insertion.^{10,13,79,80} These clusters are also still arranged in such a way as to result in the same behavior as a chain to produce a net magnetic dipole moment.^{10,13,79,80}

Figure 8 Magnetic Field of a Magnetosome Chain in a Cell of Magnetospirillum magnetotacticum

Magnetic field lines (black) superimposed on magnetosomes (bright regions) derived from electron holography, or mapping the interference pattern observed during electron microscopy. The field lines passing through the magnetosomes indicates the chain acts as a single magnetic dipole. (Figure from Bazylinski 2004)

Magnetosome Genes

While the characteristic that defines MTB as a group is the phenotype that results from magnetosomes, the crystal mineral composition and arrangement vary with each species producing crystals with a morphology unique to it.^{9,12,16} The magnetosome crystal size, mineral composition, purity, morphology and composition are tightly controlled by the proteins embedded in the magnetosome membrane.^{4,12,16,35} These embedded proteins are coded for by

the bacterium's complement of magnetosome-associated membrane genes referred to as the *mam*, *mms* and *mtx* genes.⁴²

The first studies to investigate the genetic determinants necessary for magnetite biomineralization in these prokaryotes were conducted with axenic cultures of the exclusively elongated cuboctahedral magnetite crystal producing⁸¹ *Magnetospirillum* (*M.*) species of the *Alphaproteobacteria*. As a result the greatest degree of established knowledge is based on this group. These studies, primarily utilizing genetic systems established in *M. magneticum* and *M. gryphiswaldense*,^{9,44,82} showed that there are, at least for the species of the genus *Magnetospirillum*, numerous genes involved in magnetosome formation that cluster together, some of which are transcribed as operons.^{82,83} This includes the *mam* genes:

A,P,Q,R,B,S,T,U,H,E,J,K,L,M,N and *O*. (Appendix Table 30)

The genes of the *mamAB* operon are involved in various necessary basic functions such as the formation of and attachment to the actin like cytoskeletal scaffolding that hold the magnetosomes in place (MamK),^{84,85} invagination of the inner membrane to form the vesicle (MamIMBLQ),^{2,86} vesicle activation and crystal maturation (MamA),^{2,16} magnetite biomineralization (MamEPMBO).^{83,87,88} Other functions include iron uptake and transport, (FeoA-like and FeoB-like,⁸⁹ MamN⁸³) crystal nucleation (MamN⁸³), electron transfer (MamT³³), small solute transport (MamH⁹⁰) and proteases (MamE⁶⁵). It was later determined through knock out experiments that the genes of the *mamAB* operon made up what is seemingly the core set of *mam* genes required for the magnetic phenotype through complete magnetosome formation.^{82,83,91} Magnetite biomineralization can be achieved with these genes alone, although notably the crystals are both smaller and misshapen.^{82,83} Not all of the genes of the

mamAB operon are still generally considered essential however, as some are missing in MTB in groups other than the genus *Magnetospirillum*. For example, although essential to the anchoring of magnetosomes to MamK, *mamJ*, which codes for a protein mediating this attachment, is not present in other MTB.^{74,84,85}

The fact that each strain produces crystals of a specific morphology unique to it, may be due to its complement of periphery magnetosome associated genes and its unique genetic background containing potentially pleiotropic genes also playing a role in biomineralization.⁹²

In addition to the *mamAB* genes, there are also less characterized accessory clusters and genes associated with magnetosome formation in various MTB species. The fact that crystals formed with only the *mamAB* operon available develop with aberrant morphology indicates that the additional genes play a role in the tight size and shape control of crystal morphology observed in MTB. For example, the 3.6 kb five gene *mms* cluster is indeed involved in the nucleation and size control of magnetite crystals.^{93,94} The approximately 2.1 kb *mamGFDC* cluster in magnetospirillum produces proteins that are also involved in size regulation of the crystals.⁶⁷ In the marine magnetococcus *Magnetococcus marinus* strain MC-1, *mamC* is, rather than part of a *mamGFDC* cluster, found in a *mamCEIH* cluster,⁵⁶ while *mamC* is found in the *mamCOP* clusters of strain BW-2 and SS-5. Yet another cluster appearing to modulate magnetosome crystal size is the *mamXY* cluster in *Magnetospirillum*⁹⁰ and the orthologous *mamDXZ* cluster in *Magnetococcus marinus*.⁵⁶ Found apart from any other magnetosome genes, *mamW* is also likely to play a non-essential role in crystal morphology.⁹⁵ The *mtx* cluster that is found in various MTB species contains genes with TPR protein homology as well as one homologous to an adenylate cyclase and therefore may be involved in signal transduction in

some way.⁵⁶ TPR (tetratricopeptide repeat)_proteins are involved in the formation of scaffolds to mediate protein–protein interactions, very often leading to the assembly of multiprotein complexes.⁹⁶

Arrangement of magnetosome genes within genomes of MTB

In not all, but the majority of MTB, most of the genes involved in the magnetic phenotype are found clustered in a stretch of genome with all of the characteristics of a genomic island, a portion of a genome containing evidence of the transfer of genetic material from another species. Such evidence includes: a different GC content from the rest of the genome, the genome section being flanked by mobile elements such as insertion sequences, transposases and integrases and tRNA genes that serve as insertion sites for integrases.^{97,98}

The magnetosome gene regions in *M. magneticum*, *M. gryphiswaldense* and *Desulfovibrio magneticus* have these characteristics.³⁸ In one of the first studied MTB, *M. gryphiswaldense*, for example, magnetosome associated genes as well as interspersed pseudogenes are contained within a genomic segment of about 45 kb and are flanked by mobile elements (Figure 9).

Figure 9 Genomic island of MSR-1

Genomic island of *M. gryphiswaldense* (MSR-1) flanked by transposases. Arrows indicate open reading frames (ORF), numbered hash marks indicate genomic position. Figure modified from Schubbe 2003

Spontaneous loss of magnetosome genomic islands or parts of them with a corresponding loss of magnetotactic phenotype have also been observed,⁹³ lending further support to the idea that some large magnetosome gene clusters are truly genomic islands.^{91,95,97} Magnetosome associated genes are typically arranged collinearly as is seen with the genes of typical operons which are transcribed as single long polycistronic transcriptional units, suggesting along with some experimental evidence that magnetosome genes may be transcribed similarly.⁹¹ This indicates that magnetotaxis may have been acquired by some MTB through horizontal gene transfer as well as by descent.⁹⁹

Phylogeny and Physiology

Phylogenetically, representatives of MTB are found in the *Alphaproteobacteria*, *Gammaproteobacteria*, *Deltaproteobacteria* classes of the *Proteobacteria* phylum, the *Nitrospira* phylum and the candidate phyla *Latescibacteria* (formerly candidate phylum WS3) and *Omnitrophica* (formerly candidate phylum OP3), although the majority that have been so far described and cultured are of the *Alphaproteobacteria*.^{30,100}

Alphaproteobacteria Class

MTB of the *Alphaproteobacteria* are facultative or obligate microaerophiles, some of which grow anaerobically. *Magnetococcus marinus* strain Mc-1, the coccoid strain MO-1, and

M. magnetotacticum strain MS-1 appear to be obligate microaerophiles.^{101,102} All alphaproteobacterial MTB tested for nitrogenase activity (nitrogen fixation) possess this trait and all necessary *nif* genes for the nitrogenase nitrogen fixation system were found to be in the genomes of *M. magnetotacticum* and *M. magneticum*.¹² They appear to make up the majority of MTB in many freshwater and marine environments,¹⁰³ and the most commonly present or ubiquitous of these are the so-called magneto cocci of the *Alphaproteobacteria*.¹⁰⁴ The two strains of magneto cocci in culture, *Magnetococcus marinus*⁵⁶ and strain MO-1¹², grow autotrophically using reduced sulfur compounds as electron donors and the reverse tricarboxylic acid cycle for autotrophy.^{104,105} *Magnetococcus marinus* also grows chemoorganoheterotrophically using acetate as a carbon and electron source.⁵⁶

Members of the freshwater genus *Magnetospirillum*¹⁰⁶ appear to be the most amenable MTB to culture (based on the overall number of isolated strains in culture) and the least fastidious with regards to growth. This latter feature has allowed for the development of genetic systems in several species of *Magnetospirillum* through which the function of magnetosome related genes can be studied.⁴¹ Three of the most studied *Magnetospirillum* species are *M. gryphiswaldense*, *M. magneticum* and *M. magnetotacticum* which have in common the ability to respire as microaerophiles using O₂ or anaerobically with nitrate via chemoorganoheterotrophic metabolism with organic acids as a carbon and electron source.^{106,107} However, *M. gryphiswaldense* is also capable of autotrophic and mixotrophic growth utilizing reduced sulfur compounds as electron donors. Ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) activity has been observed and the genes coding for RuBisCO type II were identified in *M. gryphiswaldense* and *M. magnetotacticum*, suggesting that these

organisms use the Calvin-Benson-Bassham cycle for autotrophy.^{22,108,109} RuBisCO, considered the most abundant protein on the planet, catalyzes the eventual conversion of CO₂ to the carbohydrate precursor 3-phosphoglycerate.¹¹⁰

Another well characterized MTB of the *Alphaproteobacteria* is the marine vibrio *Magnetovibrio blakemorei* strain MV-1.¹¹¹ Its metabolism is similar to freshwater magnetospirilla in that it also respire oxygen, nitrate or additionally nitrous oxide as terminal electron acceptors in respiration.¹¹¹ It grows chemoorganoheterotrophically with organic acids as well as some amino acids as carbon and electron sources,¹¹¹ and chemolithoautotrophically with reduced sulfur compounds as electron donors and the Calvin-Benson-Bassham autotrophy cycle,^{36,111} with nitrogenase activity indicating nitrogen fixation in both modes of growth.¹¹¹

Magnetospira thiophila (strains MMS-1 and QH-2) are obligate microaerophiles that heterotrophically utilize organic acids as carbon and electron sources. They also exhibit chemolithoautotrophic growth using thiosulfate and nitrogenase activity.¹²

All known MTB of the *Alphaproteobacteria* biomineralize magnetite crystals that have cuboctahedral or elongated prismatic morphologies,^{1,86,112} usually only producing the crystals under microaerobic or anaerobic conditions^{16,101,102}

Deltaproteobacteria Class

The MTB of the *Deltaproteobacteria* include rods,^{50,98} vibrios,⁹⁸ and even multicellular magnetotactic prokaryotes (MMPs) that consist of 10-60 genetically similar, communicating interdependent cells.^{49,80,113} The Deltaproteobacterial MTB are able to grow heterotrophically by reducing sulfate and almost all cultured species exhibit nitrogenase activity and therefore likely fix atmospheric nitrogen. They are able to grow in alkaline, anaerobic, microaerophilic and saline environments.^{4,12}

Of most interest to this work, the MTB of the *Deltaproteobacteria* biomineralize magnetite, greigite or both, although notably the crystal morphology is bullet or tooth shaped.⁴⁹

Gammaproteobacteria Class

The only finished MTB genomes of the *Gammaproteobacteria* are those of BW-2 and SS-5. They are both rods that grow chemolithoautotrophically, using thiosulfate and sulfide microaerobically as electron donors. Both use the Calvin-Benson-Bassham cycle for autotrophy, as evidenced by RuBisCO activity¹ and the presence of the necessary RubisCO genes.

Both notably biomineralize octahedral magnetite, similarly to the MTB of the *Alphaproteobacteria*.

Figure 10 Flagellar patterns on cells of strains BW-2 and SS-5

Transmission electron microscopy image of BW-2 (a) and SS-5 (b) cells. White arrows indicate magnetosome chains. The inset image depicts the bundle of seven flagella of BW-2.

Nitrospirae Phylum

As no MTB of the *Nitrospirae* have been successfully cultivated, less is known about their metabolism although they are likely as diverse as other groups as they inhabit the same niches and are observably as diverse in other regards. Morphologically, all so far described include rods,^{39,114} ovoids⁵¹ and vibrio.⁹⁸ They inhabit anoxic and microaerobic sediment

environments in fresh and brackish water of moderate to moderately high temperatures.
^{12,51}(up to 63°C)

Of importance to this work, all known MTB of the *Nitrospirae* biomineralize bullet shaped magnetite.^{27,51,53,115–118}

Phylogenetic significance of magnetosome morphology

It appears clear that in at least some cases the magnetic phenotype was acquired through horizontal gene transfer events.⁵⁶ Evidence for this includes gene complement, synteny, the fact that the magnetosome related genes of some MTB are clustered with all of the characteristics of genomic islands including transposable elements and the entire gene set has been observed to spontaneously be lost.^{56,119}

Although the defining characteristic of MTB as a group is the formation of magnetosomes, because this process is under such strict genetic control, there is considerable variation of this phenotype between phylogenetically unrelated species. If it were generally the case that the magnetotactic trait had been transferred in this way between different phylogenetic groups, all of the various crystal morphologies would likely be present in the various phylogenetic groups of MTB, which is not what has been observed.³⁰

However, magnetosome crystal morphology distribution among MTB comports with acquisition of the trait through descent. Production of the octahedral, prismatic and rectangular crystals that require stricter control over the biomineralization process are localized

to the more recently diverging *Alpha* and *Gammaproteobacteria*. The bullet shaped magnetite and irregular greigite crystals are produced within a monophyletic clade of the *Deltaproteobacteria*, the *Nitrospirae*, and the candidate division OP3 which are the most deeply branching groups.^{100,120}

In addition, the core set of genes required for the magnetic phenotype is conserved in all MTB with enough sequence variability to track the descent of the trait and evolutionary differentiation of the different morphologies.³⁰ When a magnetosome gene phylogenetic tree is constructed and compared with the 16s rRNA gene sequence phylogenetic tree the evolution of the core magnetosome genes appears to be congruent with the evolution of the MTB species themselves, lending strong support to the view that the magnetic phenotype evolved in current MTB species from a common magnetic ancestor via descent.¹⁰⁰

In light of these evidences it becomes clear that in the majority of cases the phenotype is very likely the result of a monophyletic origin in a last common ancestor with many genes controlling crystal morphology evolving after the branching of the groups.^{86,100,116}

The MTB of the *Delaproteobacteria* and *Nitrospirae* are more deeply branching phylogenetically and have fewer known magnetosome associated genes than the *Alpha* and *Gammaproteobacteria*,²¹ therefore it follows that they would have less precise control over the biomineralization of their magnetosome crystals as is actually observed. Acquisition of the phenotype through descent also comports with the strong correlation between crystal morphology and phylogeny^{21,86} with the *Nitrospirae* and *Deltaproteobacteria* producing bullet

or tooth shaped crystals and the MTB of the *Alphaproteobacteria* and *Gammaproteobacteria* producing cuboctahedral and elongated prismatic crystals.

Utility of Magnetotactic Bacteria Research

MTB cells and their magnetosomes have a unique combination of magnetic, physical and optical properties that can be used for many applications. Representing the oldest form of biomineralization on the planet,⁹ these bacteria are an excellent system in which to study controlled biomineralization and the genetic components involved. The production of magnetosomes may have great potential in many biotechnological and nanotechnological applications due to the precise morphological and chemical nature of the magnetosome crystals they produce and the fact that they are membrane bound.^{10,28} The membrane allows for aqueous dispersion in biological systems while enabling the binding of proteins via embedded antibodies for magnetic purification or chemiluminescence enzyme immunoassays. A potential clinically relevant application includes targeted magnetosome mediated drug delivery whereby a drug can be targeted within the body with a focused magnetic field. Additionally, in an oscillating focused magnetic field, magnetosome crystals produce heat, potentially facilitating the selective thermal destruction of malignant tissues. In addition, this form of prokaryotic biomineralization is a simpler and more tractable model system than bone in which to elucidate the basics of biomineralization.

MTB could also offer insight into some paleoecological and exobiological paradigms as these crystals are uniquely biomineralized such that they do not occur abiotically and remain intact over long periods of time under certain conditions in specific natural environments. MTB also present a unique opportunity to study molecular evolution as the phenotype has been identified in across taxonomical groups including the *Alpha* and *Deltaproteobacteria*³³ as well as the *Nitrospirae*¹¹⁵ and the candidate OP3 division.¹²⁰ Only two so far have been identified in the *Gammaproteobacteria*, strains SS-5 and BW-2,¹ though neither has yet been thoroughly characterized. Genetic data regarding a number of other distantly related MTB are available, mainly from the cubooctahedral and elongated prismatic magnetite producing *Alphaproteobacteria* species and the bullet-shaped magnetite and/or greigite producing *Deltaproteobacteria*. There are only seven completed MTB genomes, limiting the genetic background information available for the magnetic phenotype.

In this study we finished, annotated and analyzed the complete genome sequences of strains BW-2 and SS-5, currently the only MTB of the *Gammaproteobacteria* isolated in pure culture. This enabled us to elucidate the gene content, sequence and synteny of the operons and MAI's of these new strains as they relate to each other and to other phylogenetically-unrelated characterized strains, as well as their genetic context, lending valuable insight into the molecular evolution and function of these unique genes as well as the mechanisms used to acquire these genes. . In chapters three and four BW-2 and SS-5 respectively will be assessed for metabolic potential based on genomic features and the gene compliment, synteny and presence or absence of genomic features indicative of the presence of a genomic island will be elucidated. In chapter five the metabolic potential and magnetosome gene compliment and

synteny of BW-2 and SS-5 will be compared to one another as well as to other MTB. The phylogeny of magnetosome-related gene sequences will be compared with strain phylogeny across phylogenetic groups in an effort to determine whether the magnetic phenotypes of these strains were acquired via horizontal gene transfer or by vertical descent. Genes already considered to be involved in magnetosome formation will be compared to identify those common to magnetite biomineralizers across phylogenetic groups as well as any differences in gene complement between the octahedral crystal-producing BW-2 and the elongated prism-producing SS-5. With these additional completed genomes available from the *Gammaproteobacteria*, a further comparative genomics approach will be more powerful in predicting novel candidate magnetotaxis genes which will be proposed in chapter five for strains BW-2, SS-5 and in other MTB species. With a more complete metabolic background, metabolic genes elsewhere in the genome could reveal pathways, reactions and enzymes responsible for supportive, synergistic or redundant functions in the biomineralization of magnetosomes, such as nitrate reductase (*nap*) gene.^{121,122}

Chapter 2 Materials and Methods

Gammaproteobacterial MTB Strains Used in this Study

Strain BW-2 was isolated from sediment collected under permit from Badwater Basin in Death Valley National Park.¹ It is a rod-shaped bacterium that is motile via a polar bundle of seven flagella at one end of the cell.¹ Cells biomineralize cubooctahedral magnetite crystals in their magnetosomes, and sulfur- and phosphorus-rich inclusions when grown in semi-solid O₂-concentration gradient ([O₂]-gradient) medium with thiosulfate as electron donor¹ (Figure 11).

Figure 11 Inclusions within cells of strain BW-2

a) Transmission electron microscope image of a cell of strain BW-2 showing cell inclusions. B) Differential interference contrast image of cells of strain BW-2 showing cell inclusions. S = sulfur inclusions, P = phosphate inclusions, (From Lefevre 2012)

Strain SS-5 was isolated from sediment taken under permit from the shore of the Salton Sea in California.¹ It is also a rod-shaped bacterium and is motile but by means of a single polar flagellum. Cells of this strain also biomineralize magnetite magnetosome crystals but with an elongated, prismatic octahedral morphology and produce phosphorus-rich inclusions¹ (Figure 12).

Figure 12 Transmission electron microscope image of cells of strain SS-5 showing cell inclusions

Differential interference contrast image of cells of strain SS-5. P = phosphate inclusions, (From Lefevre 2012)

Growth Conditions

BW-2 and SS-5 were grown in semi-solid [O₂]-gradient medium optimized for their individual growth. The most effective formula for the growth of strain BW-2 contained a base of salts consisting of 348 mM NaCl, 21.3 mM MgCl₂•6H₂O, 22.8 mM Na₂SO₄, 3.25 mM CaCl₂•2H₂O and 7.73 mM KCl per liter of distilled, deionized H₂O (ddH₂O). To this was added per liter of medium, 0.2 mL aqueous resazurin, 5 mL Wolfe's mineral solution¹²³, 15 mM NaHCO₃, 5.6 mM NH₄Cl and 1.6 g Bacto-Agar (Difco, Burlington, NC). The pH was then adjusted to 7.0 and the medium was autoclaved. After autoclaving, the pH of the medium was again adjusted to pH 7.0 aseptically, if necessary, and the following sterile solutions were added

aseptically: 0.5 mL of vitamin solution¹²⁴, 1.8 mL of 0.5 M phosphate buffer (pH 7.0), 3 mL 0.01 M FeSO₄, 3 mL 40% sodium thiosulfate, 0.4 g of freshly made, filter-sterilized cysteine and 5 mL 100 mM Na₂S. The medium was again adjusted to pH 7.0 if necessary and dispensed into screw-capped test tubes to approximately 80% of their volume, leaving 20% of the volume as an air headspace. Cells were inoculated into this medium by syringe just below the OAI as indicated by the colorless-pink interface (resazurin is pink in color when oxidized and colorless when reduced ref). Cultures were then incubated at 25°C in the dark.

The growth medium used strain SS-5 was similar to that of BW-2 except the basal salts consisted of: NaCl 646.8 mM, MgCl₂•6H₂O 26.56 mM, Na₂SO₄ 38 mM, KCl 12 mM, and CaCl₂•2H₂O 3.4 mM per liter of dd H₂O. The other reagents were the same as for strain BW-2 and the medium was inoculated and incubated as described above.

Isolation of DNA from Cells

When DNA was to be isolated, 825 mL of medium was prepared in a 1 L flask and 1.2 g of low melting point agarose (ThermoFisher, Waltham, MA) was substituted for Bacto-Agar. In the presence of sulfide this method facilitated dense cell growth as floating aggregates that formed at the surface in addition to a layer of cells at the OAI.

DNA was extracted after pelleting cells by centrifugation at 13.4 RCF at 4°C then removing the pellets by pipette from beneath the concentrated agarose that settled on top of the pellet. Cell pellets were then combined and re-centrifuged and any additional agarose was

melted with warm sterile water and removed by pipette to keep it from clogging spin columns used in genomic DNA (gDNA) extraction kits or from carrying over in the aqueous phase during the phenol chloroform extraction.¹²⁵ Kits used for isolation and cleanup were Qiagen Blood and Tissue, (Germantown, MD) Qiaquick pcr purification kit (Qiagen, Germantown, MD) and Zymo clean and concentrator. (Irvine, Ca.) DNA quality was determined by agarose gel electrophoresis and Agilent Bioanalyzer and quantification was by Nanodrop ND-1000 spectrophotometer and Qubit 2.0 Fluorometer.

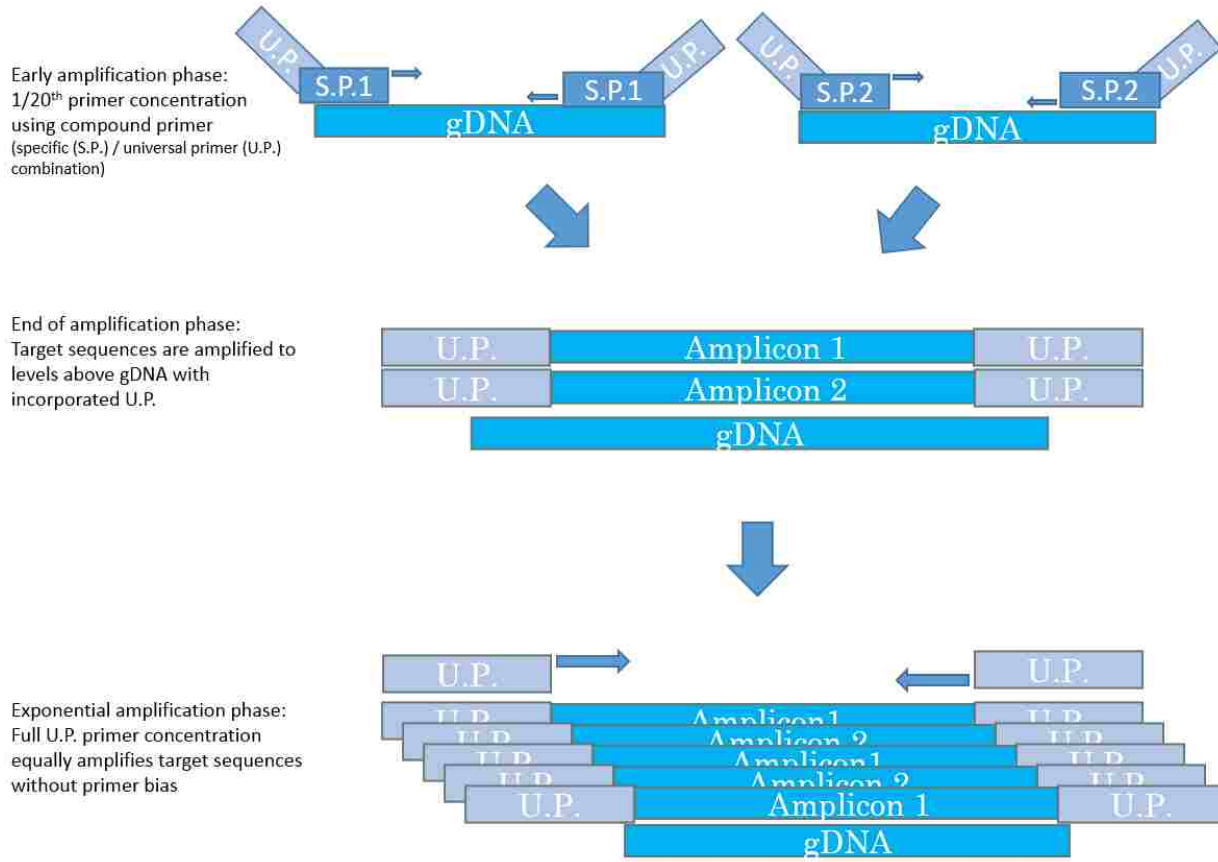

Genome sequencing, assembly, annotation and scaffolding.

Four-five-four genome sequences from strain SS-5 were obtained in one run on the GS FLX sequencing system. For strain BW-2, 800x coverage of paired end Illumina sequence with 300 bp inserts were obtained in three runs on the Illumina MiSeq platform after library prep with Illumina Nexterra XT (San Diego, Ca) and KAPA Biosciences (Wilmington, Ma) Library Preparation Kits. Pacific Biosciences (PacBio)¹²⁶ long reads were obtained on the PacBio RS Single Molecule Real-Time (SMRT) sequencing platform, using three SMRT cells for BW-2 to achieve 333x coverage. CLC Genomics Workbench (CLC Bio-Qiagen, Aarhus, Denmark) was then used to correct errors in the reads using a 75% subset of the input reads before de novo assembly, which has been shown to yield results as accurate as correcting with the higher accuracy Illumina reads.^{127,128} The assembly was done using the automatic word size and contig polishing settings, minimum word coverage of two, and minimum contig length of 2,000. Scaffolding was then performed with PacBio long reads using CLC Bio Genomics Workbench

8.5.1 with the Genome Module 1.5.2 contig alignment, joining and splitting functions. This was then repeated 5 more times starting with different datasets with a consistent result before Illumina reads were mapped to it for further error correction. Illumina assemblies were also done with the SPAdes 3.5.0,¹²⁹ Velvet¹³⁰ and CLC Bio Genomics Workbench 8.5.1 (CLC Bio-Qiagen, Aarhus, Denmark) assemblers as well as the SABIA¹³¹ and MaGe¹³² annotation platforms in order to achieve the highest N50 and lowest number of contigs in order to compare assemblies for scaffolding purposes. Contig genomic features were annotated using the RAST^{133,134} and MaGe genome annotation environments and potential promoters were identified using BPROM.¹³⁵ The genomes were searched for prophages using the PHAST server tool.¹³⁶ Circular chromosome maps were generated by the CG View web server application¹³⁷ and modified in Power Point (Microsoft, Redmond, WA). Phylogenetic tree of MTB species was constructed in CLC Genomics workbench and modified in Power Point. At the scaffolding stage, this also enabled targeted PCR across contig gaps based on conserved genomic features that appeared to be split by contig breaks such as conserved operons and the magnetosome associated cluster. Singlet PCR was performed using GoTaq Green PCR master mix. (Promega, Madison, WI) Primers were designed with tools including Primer3,¹³⁸ OligoAnalyzer (PrimerQuest® program, IDT, Coralville, USA. Retrieved 12 December, 2012. <http://www.idtdna.com/Scitools>) and Primer-BLAST^{139,140} utilizing nearest-neighbor, mono and divalent cation, oligo and dNTP concentration parameters. Primers were constructed by Integrated DNA Technologies. (Coralville, IA) Resulting amplicons were Sanger sequenced on the ABI 3730xl DNA Sequencer then aligned and joined to contigs using the Geneious 7.1.9 platform (<http://www.geneious.com>, Kearse et al., 2012). Contigs joined in this way were

designated as trusted contigs and were subsequently used as additional SPAdes input in re-assembly and as quality checks for assembly and scaffolding based on PacBio reads. When conserved regions at contig ends were no longer identified in BW-2, the Mauve whole genome alignment algorithm¹⁴² was employed to guide further targeted PCR attempts, using the nearest 16s rRNA neighbor with a sealed genome, *Thioalkalivibrio versutus*,¹⁴³ which is 89.5% similar in its 16s rRNA gene sequence to strain BW-2. When there were no longer data to guide PCR primer placement, exploratory PCR methods were employed including a modification of a universal multiplex primer PCR method that has been previously described¹⁴⁴⁻¹⁴⁶ using the Platinum Multiplex PCR master mix by Thermo Fisher Scientific. (Waltham, MA) In this method, a sequence not occurring in the target genome is identified and its complimentary sequence is incorporated at the 5' end of primers specific to sites of interest in the target genome to form a compound universal primer/specific primer. The compound primers can then be pooled in a multiplex PCR reaction at 1/20th of standard concentration (0.5 μM) for a 20-plex reaction, along with the usual standard concentration of the universal primer. (10 μM) As the reaction proceeds, the specific primer portion of the compound primers generate amplicons during the early phase to serve as additional template for regions of interest. These amplicons have incorporated the complimentary sequence to the universal primer sequence. As the reaction continues into exponential amplification the compound primers are exhausted enabling the universal primer alone to take over in the amplification reaction (Figure 13). This eliminates amplification bias among specific primers of differing efficiencies and allows amplicons to equally amplify. In eliminating amplification bias during the exponential phase of the reaction in this way, no primer is outcompeted for reagent and all possible amplicons are produced.

Figure 13 Universal Primer Multiplex PCR

A suitably unique sequence for use as the universal primer was identified by using restriction sites indicated as non-cutting sites in a virtual digest performed in Geneious, allowing the universal primer to also serve as a cut site should the amplicon need to be incorporated into a plasmid for subsequent sequencing. Resulting amplicons were mapped to contig ends in Geneious after processing with Mixed Sequence Reader,¹⁴⁷ an algorithm designed to separate overlapping allelic amplicons using genomic sequence as a reference to call second peaks in sequencing chromatograms. PCR was then repeated with primers at locations indicated in this way in order to obtain more accurate amplicon sequences for use in

spanning the inter-contig gap. In order to increase the likelihood an amplicon would occur, a second universal primer was then incorporated as an adapter ligated to the ends of 1-2 kb gDNA fragments after digesting gDNA with restriction endonucleases that were determined to cut every 1-2kb in the genome, similar in principle to vectorette PCR.^{148,149} Appropriate restriction sites were identified by importing the results of a virtual digest performed in Geneious into Excel (Microsoft, Redmond, WA) and graphing those with an amount of cut sites sufficient to digest the 3.2Mb genome into 1-2kb fragments. Plotting the fragments in this way identified restriction sites for elimination from consideration that clustered in the genome to yield an uneven fragment size distribution outside of the desired size range.

The three restriction enzymes indicated in this way as ideal candidates were Aval, BglI (Promega, Madison, WI) and EcoRII. (New England Biolabs, Ipswich, MA) Single stranded PCR^{150,151} was also employed with two primers situated close together on the same strand and in the same direction. The use of a second primer biased the reaction to amplify the intended target sequence rather than amplification due to nonspecific binding of the primer. Finally, to resolve remaining scaffolding errors, Illumina paired end reads were mapped back to contigs in CLC Genomics Workbench to identify pronounced read disagreement sites at which contigs were split. The mapped, paired Illumina reads were then used in Genomics Workbench to align read overhangs and identify broken pairs so as to identify the final remaining contig end alignments.

Chapter 3 Results from the Genome of Strain BW-2

General genomic features

The genome of strain BW-2 consists of a circular chromosome of 4,103,727 bp with no evidence of extrachromosomal elements (Figure 14). The average G+C content is 52.6% and there are 3,791 coding sequences including those encoding 41 tRNAs, 2 sets of 5S/16S/23S rRNAs and 1,572 hypothetical proteins. The average coding sequence length is 990.49 bp, representing 90.99% of the genome as coding sequence. (Table 1, 2, 3) The 269 nt region containing the probable OriC is positioned at noon on the circular chromosome map (Figure 14). It is immediately downstream of the *dnaA* gene and followed by *dnaN* with a GC skew to 0 in the same area. The region contains 6 *Escherichia coli dnaA* box sequences with 0-1 mismatches and a 21 bp sequence of 90% identity to that found in the SS-5 probable OriC that produces no hits when blasted against NCBI databases (Figure 15).

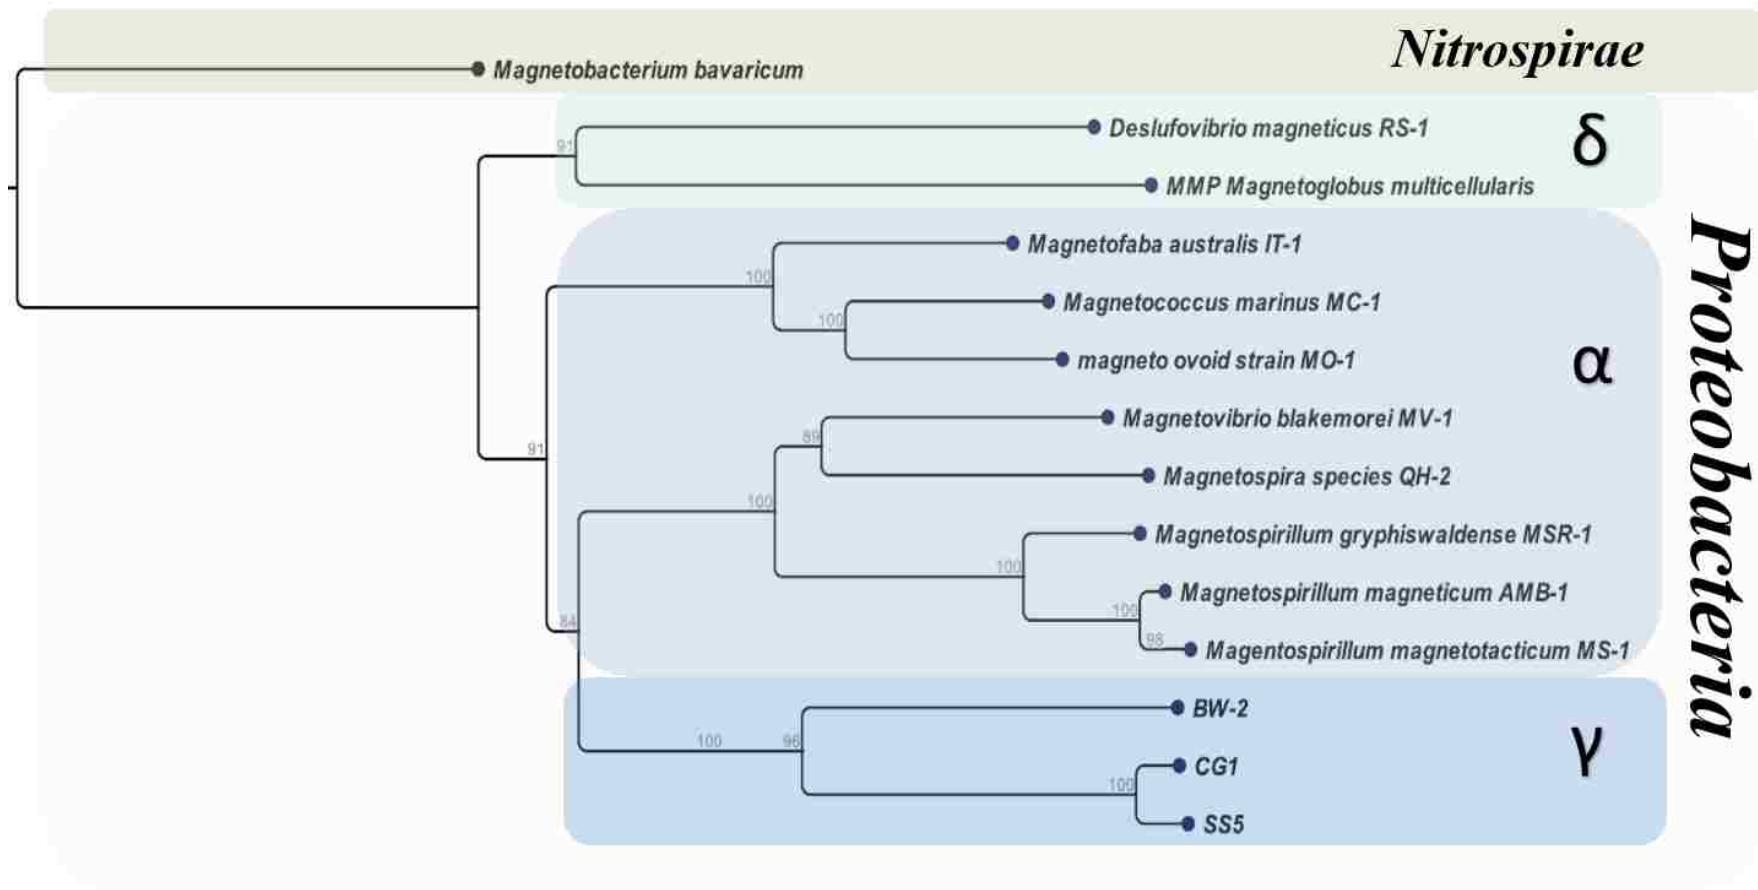

Figure 15 Probable Origin of Replication in the Genome of Strain BW-2

The *Escherichia coli* perfect DnaA box (ttatccaca) was searched for with no more than one mismatch. DnaA boxes are underlined and in bold. 21 bp alignment of BW-2 and SS-5 probable OriC sequences is in bold. (2 mismatches at 90.4% identity, no hits when blasted against NCBI)

Phylogenetically, strain BW-2 belongs to the order *Thiotricales*.¹ Its most closely related MTB strain is SS-5 with a 16s rRNA gene sequence identity of 87.58%. The next closest MTB strain is the newly isolated and as yet unfinished genome of another magnetic bacterium of the *Gammaproteobacteria*, strain CG-1 which belongs to the order *Chromatiales*, at 85.12% 16s rRNA gene sequence identity (Figure 16).

Some Important Metabolic Features and the Genome of strain BW-2

Autotrophy: CO₂ Fixation

Strain BW-2 has been shown to grow chemolithoautotrophically using sulfide and thiosulfate as electron donors and sodium bicarbonate/CO₂ as the major source of carbon.¹ Coding sequences for 31 genes involved in carbon fixation were identified in the BW-2 genome, including two complete sets of form I “green-like” ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) genes for carbon fixation indicating it has the potential to employ the Calvin-Benson-Bassham cycle for autotrophy¹ (Figure 17). Both sets are in the same region 6,382 bp apart. The upstream set is incorporated into a full α -carboxysome operon^{23,32,152–154} with shell protein gene *csoS2*, carbonic anhydrase encoding *csoS3*, shell protein genes *csoS4A*, *csoS4B*, *csoS1A* and *csoS1B*, a bacterioferritin, a possible dehydratase, a hypothetical gene and a RuBisCO operon transcriptional regulator gene in the given order (Figure 17). Carboxysomes are polyhedral intracellular compartments some of which are known to be involved in carbon fixation by enclosing and concentrating RuBisCO, (Figure 18) making up over 60% of the carboxysome protein.^{32,154} The carboxysome specific carbonic anhydrase, *csoS3*, is thought to catalyze cytoplasmic bicarbonate to CO₂ which is concentrated within the carboxysome and is the main substrate for RuBisCO.¹⁵⁵ This results in the favoring of the carboxylase reaction over the oxygenase reaction, leading to the production of glyceralate-3-phosphate for use in central carbon metabolism.^{152,153} One copy of a bicarbonate transporter gene *bicA* with high homology to the cyanobacterial Na⁺-dependent HCO₃⁻ transporter *bicA* is also present 3 kb upstream of this carbon fixation gene cluster. Downstream is the second set

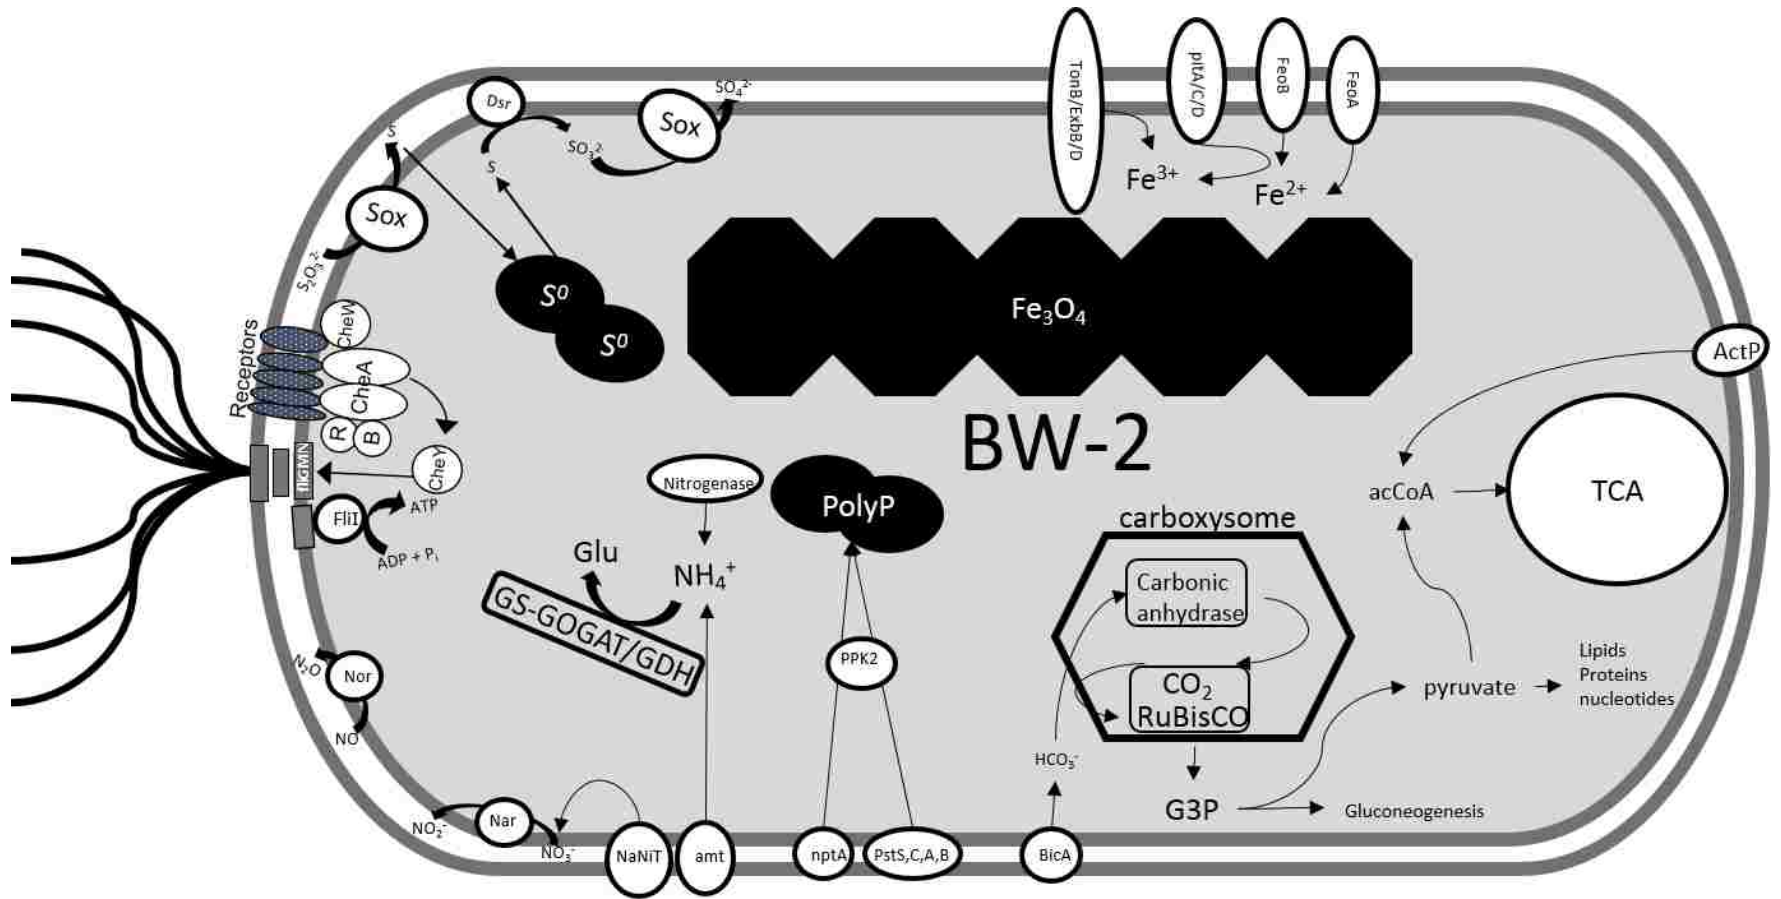

of *cbb* genes in the order *cbbL* large chain, *cbbL* small chain, a hypothetical CDS, *cbbQ*, *cbbO*, an adenosylhomocysteinase and *csoS1D*. Although the full complement of genes necessary for their expression is present, carboxysomes have not yet been visualized in BW-2.

Figure 17 Rubisco and Carboxysome gene Regions in the Genome of Strain BW-2

Arrows represent genes, numbered hash marks represent genomic location in bases relative to origin of replication. The genes *csoS2*, *csoS4A*, *csoS4B*, *csoS1A*, *csoS1B* and *csoS1D* code for carboxysome shell proteins *csoS3* encodes carbonic anhydrase, *hyp* = hypothetical gene

Figure 18 Metabolic Overview Diagram of Strain BW-2

Central Carbon Metabolism

The gene complement for the tricarboxylic acid cycle (TCA) cycle is complete in the genome of strain BW-2. Not surprisingly, in light of the presence of the complete RuBisCO system, genes enabling the TCA cycle to operate in the reductive direction were not found. Genes necessary for carbon flow through glycolysis are present, however gluconeogenesis is either nonfunctional due to a missing fructose-1,6-bisphosphatase or more likely catalyzed by an unknown nonorthologous enzyme, in that the largest group of confirmed and predicted non-homologous isofunctional enzymes is within carbohydrate metabolism.¹⁵⁶

The gene for the acetate transporter acetate permease (*actP*) is present along with those encoding all necessary enzymes to convert acetate to acetyl-CoA making it available to the TCA cycle. Previous attempts to grow strain BW-2 heterotrophically on acetate were however unsuccessful¹ indicating this pathway may not be functional or is not so under currently used culture conditions. Some enzymes for sugar metabolism are present as would be expected for the resupply of intermediates in anabolic pathways. However, consistent with the observed obligate chemolithoautotrophic growth, no identifiable sugar transporter genes are present in the genome of strain BW-2.

Iron Metabolism

As biomineralizers of magnetosome iron crystals, MTB contain several orders of magnitude more iron than non-magnetotactic bacteria with their dry mass composed of up to 3% iron.¹⁶ In fact, some MTB strains have been known to synthesize up to 16.7 mg magnetite liter⁻¹ day⁻¹.¹⁵⁷ Therefore, Fe metabolism is obviously important to MTB including its uptake, transport, oxidation and reduction.

The genome of strain BW-2 contains genes encoding an iron uptake ABC transporter, two copies each of *pitA* and *pitC* and three copies of *pitD*. In addition, there are ferrous iron transport proteins FeoA and FeoB. BW-2 also has the *tonB/exbB/exbD* complex for ferric-siderophore transport and two non-ribosomal peptide synthetases coding sequences for siderophore synthesis, one contiguous with an amino acid ABC transport gene cluster and the other contiguous with another non-ribosomal peptide synthetase. The existence of other iron transport mechanisms can't be discounted. For example, there is an *yfeX* gene present, the product of which has been shown to promote Fe extraction from heme and participate in an encapsulated Fe acquisition system.¹⁵⁸ A heavy metal transporter was also identified as well as many uncharacterized proteins in BW-2 that are highly homologous to cation transporters in other bacteria. A coding sequence for the iron uptake, oxidation and storage protein bacterioferritin^{159,160} was also identified adjacent to RuBisCO genes as well as a ferric iron uptake regulator protein (*fur*) gene. The BW-2 genome also contains the *mam* genes involved in iron redox control during magnetosome synthesis, *mamBMEPTH*.

Nitrogen Metabolism

Cells of strain BW-2 have been shown to possess nitrogenase activity as evidenced by their ability to reduce acetylene under nitrogen-limited conditions suggesting they fix atmospheric dinitrogen (N_2).¹ The complete nitrogenase regulon is present in three genomic areas (Figure 19). The regulon consists of five separate operons including the *nifKDHTNY* operon which encodes the nitrogenase enzyme and is immediately upstream of *nifENX* which encodes nitrogenase cofactors. The *nifBQ* operon along with nitrogenase associated ferredoxins, is a little over 0.57 Mb upstream, and also encodes nitrogenase cofactors. The nitrogenase expression regulation operon *nifLA* is located immediately upstream of the *nifUSVM* operon and is responsible for the processing of a nitrogenase subunit and the *nifWZ* operon involved in electron transfer to nitrogenase when functioning. This cluster of *nifLA*, *nifUSVM* and *nifWZ* is about 1.76 Mb upstream of the *nifENX* and *nifHDKTNY* gene clusters. A *nifJ* gene encoding the pyruvate-flavodoxin-oxidoreductase protein involved in the electron transfer to nitrogenase, does not appear to be present although there are three nitrogenase associated pyruvate-ferredoxin-oxidoreductase enzyme coding genes in strain BW-2 to fulfill this role.

Figure 19 Nif Regulon of Strain BW-2

Arrows indicate genes, brackets indicate operons, and numbers at hash marks indicate genomic position by base pair numbered from origin of replication

Strain BW-2 utilizes ammonia as a source of nitrogen for growth. Coding sequences were found for an ammonium transporter gene, *amt*, as well as for glutamine synthetase/glutamate synthase (bacteria-like GS-GOGAT cycle) and glutamate dehydrogenase for the assimilation and fixation of ammonia when available in the environment (Figure 18). Strain BW-2 does not appear to be capable of using nitrate as a sole source of nitrogen for growth as genes for an assimilatory nitrate reductase were not identified.

Denitrification is the sequential dissimilatory reduction of nitrate or nitrite to a gaseous end product (nitrous oxide or dinitrogen) and is a globally important environmental biogeochemical process since it results in the loss of fixed nitrogen from an ecosystem.^{101,121,161} Strain BW-2 appears to have only part of the complete denitrification pathway. According to its genome, strain BW-2 has the potential for anaerobic growth using certain nitrogen oxides as terminal electron acceptors. There are two nitrate/nitrite transporter genes present immediately upstream of the respiratory nitrate reductase *narGHJI* genes for the reduction of nitrate to nitrite (Figure 21). Despite the presence of the genes for the dissimilatory reduction of nitrate to nitrite, it is noteworthy that attempts to grow strain BW-2 anaerobically with nitrate in the laboratory were unsuccessful. Strain BW-2 appears to be missing any type of dissimilatory nitrite reductase preventing the further reduction of nitrite to nitric oxide. However, the genes for nitric oxide (NO) reductase *norCBDQD* are present and located immediately upstream of the nitric oxide reductase regulatory and activation genes potentially allowing strain BW-2 to reduce nitric oxide to nitrous oxide (N₂O) (Figure 20). No evidence for a nitrous oxide reductase (*nos* genes) was found in the genome of strain BW-2.

NO Reductase genes

Arrows indicate genes, numbers at hash marks indicate genomic position by base pair numbered from origin of replication

Sulfur Metabolism

As a sulfide- and thiosulfate-oxidizing bacterium, strain BW-2 has numerous genes related to sulfur metabolism scattered throughout its genome. Coding sequences were found for the sulfur-oxidation system SOX encoded by *soxAX*, *soxYZ*, *soxB*, the thioredoxin encoding gene *soxW* and the sulfide dehydrogenase encoding gene *soxF*. Five copies of *soxF*, three copies of *soxW* and a copy of homologous protein *soxH* are also present. The genes *soxCD* are absent, typical of other *Gammaproteobacteria* that oxidize sulfur using the SOX system.⁵ It has been suggested that sulfur or polysulfide is the product of the SOX reactions without *soxCD*⁵ when thiosulfate is the substrate. Although it has also been observed in some organisms that when thiosulfate is not present, *soxCD* is not expressed.¹⁶² This might explain why cultures containing thiosulfate as the sole electron donor result in cells of BW-2 containing sulfur inclusions, but do not produce them initially in cultures when the energetically preferable sulfide is included in the medium. Once a culture with both sulfide and thiosulfate ages and becomes depleted of the more favorable sulfide, (as evidenced by the reduced intensity of the distinct sulfide odor), cells begin producing the inclusions presumably upon switching to the lower energy thiosulfate (Figure 18). As a culture with cells containing inclusions ages, the inclusions are then observed to deplete until they disappear, indicating a switch to stored S^0 once the higher energy exogenous sulfide and thiosulfate are depleted. It has been demonstrated in some strains of chemolithoautotrophic sulfur-oxidizing bacteria that these sulfur globules are formed as intermediates, and are then further oxidized by proteins encoded by the Dsr reverse-acting sulfite reductase system, that include proteins closely related to dissimilatory sulfite reductases that operate in the oxidative direction.^{5,163} A complete set of

the 16 Dsr system encoding genes including those for the membrane complex DsrMKJOP and the dissimilatory sulfite reductase DsrAB, as well as DsrCC4EFHLNRS. Once sulfur is converted to sulfite in this way it can then be further oxidized to sulfate by the SOX system.⁵ It is also possible that the YedYZ membrane associated reductase (often annotated as sulfite oxidase) is active in the reduction of sulfur species as, although its functions are largely unknown it has been shown to act upon sulfur containing substrates.¹⁶⁴

No genes for sulfate reduction, either assimilatory or dissimilatory, were identified. Reduced sulfur species required for assimilatory metabolism such as sulfide or cysteine are likely acquired exogenously.

Central Phosphate Metabolism

As phosphate is a major growth limiting resource in most aquatic ecosystems, microbes in these habitats generally have well-developed phosphate acquisition systems. Cells of strain BW-2 produce numerous phosphate inclusions¹ and have numerous phosphorous metabolism genes. In the interest of acquiring phosphate from the environment, BW-2 has 13 phosphate transport system genes. Among them are coding sequences for the high inorganic phosphate affinity PstSCAB transporter complex as well as the PhoR and PhoB two component regulatory system that make up the PHO regulon. Limiting phosphate conditions lead to the autophosphorylation of the sensory kinase PhoR which activates PhoB by phosphorylation (Figure 22). PhoB is a positive transcription regulator of the phosphate regulon that is present in 5 copies in BW-2. In non-phosphate limiting conditions, PhoB may in turn inhibit the kinase

activity of PhoR, leading to interaction of PhoR and PhoU to inhibit PhoR and dephosphorylate and inactivate PhoB.^{165,166} BW-2 also has multiple copies encoding an ATPase related to phosphate starvation-inducible protein, PhoH, that may be involved in lipid and phospholipid metabolism and RNA modification.¹⁶⁷

Additionally, the BW-2 genome contains genes that encode an NptA Na⁺-dependent phosphate transporter. Phosphate inclusions result from the polymerization of phosphate mediated by a polyphosphate kinase,^{23,32,166,168} which is present in BW-2 as *ppk2*. (Figure 18)

Polyphosphate kinase and exopolyphosphatase are the enzymes typically involved in the production of phosphate granules. Coding sequences for both enzymes were found each as two copies in the genome of strain BW-2.

Figure 22 PHO System Regulation

Pi limited

In phosphate limiting conditions PhoR activates by autophosphorylation, then in turn activating by phosphorylation PhoB which induces transcription of the Pst phosphate transporter regulon

Not Pi limited

When phosphate availability is not limiting to growth, PhoB may inhibit the autophosphorylation of PhoR, leading to its dimerization with PhoRU, further inhibiting the activity of PhoR

Transporters

There are 128 membrane transport related coding sequences in the genome of BW-2, typical of the number expected in an autotrophic prokaryote.^{23,169} Of these, 11 are ABC transport genes coding for one full and two partial ABC transporters. Among those identified were complete set of genes representing a branched chain amino acid ABC transport system, *livFGMHJ* and the associated high-affinity leucine-specific periplasmic binding protein LivK. There is also a double copy of the PhnD phosphate binding periplasmic subunit of the alkylphosphonate ABC transporter present in BW-2, but without the other components. Another two coding sequences in BW-2 homologous to an ABC transporter involved in

oligopeptide transport was also found to be partially present in SS-5. In BW-2, there are permease subunits *oppB* and *oppC*, and no subunit *oppA*, indicating loss of the other components due to genomic rearrangement since the last common ancestor of the two strains.

Three Na⁺ transporters were identified, including a complete set of a seven subunit Mrp (A-G) Na⁺/H⁺ transporter, the Na⁺/H⁺ antiporter NhaD in 2 copies, as well as the NptA Na⁺ dependent phosphate transporter.

74 protein secretion transport related sequences are present in BW-2, including 31 type IV protein encoding genes for pilin and fimbriae synthesis.

31 type I proteins for autoaggregation and biofilm formation are present in BW-2 in multiple copies. There are 20 copies of T1SS secreted agglutinin alone in addition to multiple copies of *lapBCE*. These systems are clearly active when growing BW-2 in sulfide containing medium with a headspace of air, as cells form floating aggregations and adhere to the side of the jar at and near the surface of the liquid phase of the medium. There are also 4 type II protein secretion genes, 2 more that are involved in translocation to the membrane and 4 twin-arginine translocation system genes for export of folded proteins.

There are 9 additional protein encoding genes involved in the transport of cations, including the Mg/Co/Ni transporter gene *mgtE*, the Mg/Co efflux transporter gene *corC* in 3 copies, and the Cu efflux protein encoding sequence *copA* in 5 copies.

18 more coding sequences are members of the previously mentioned Ton/Tol transport system. Three of these are involved in Fe siderophore transport. This includes coding sequences for the periplasmic binding protein TonB in 2 copies, the transport protein TolQ in 3

copies, TonR Ferric receptor in 4 copies and TolR siderophore transport protein in 3 copies. Also identified are sequences coding for the TolQ proton channel, the TolB colicin uptake protein, and the heme uptake receptor TonR in 4 copies.

Chemotaxis and signal transduction

There are multiple protein coding sequences for the versatile cyclic second messenger cAMP signal in strain BW-2. Genes were identified that code for the cAMP receptor protein FNR, multiple copies of the cAMP binding protein CGA and 14 copies of an adenylate cyclase.

There were also genes identified as encoding proteins with redox sensor PAS/PAC domains along with GGDEF and EAL domains which are involved in the synthesis and phosphorylation of cyclic second messengers.⁶⁰ These proteins react to their redox environment as assessed by their PAS/PAC domains. In this case by synthesis (GGDEF) and phosphorylation (EAL) of the second messenger cyclic di-GMP.¹⁷⁰ 61 of these redox sensor signaling proteins were identified in BW-2 in addition to 2 with the PAS/PAC redox sensing domain only.

As an aerotactic microbe, BW-2 has the gene coding for the aerotaxis receptor protein Aer. The BW-2 genome also contains many copies of genes coding for the methyl accepting chemotaxis proteins. 35 are identified in BW-2, including *tsr*, the methyl transferase CheR, and the CheC inhibitor of methyl accepting chemotaxis proteins. There are many copies of genes encoding the CheW/CheA/CheY system for signal transduction to the flagellum including CheR

and CheB, as well as the chemotaxis response phosphatase CheZ. The Che system transduces signal to flagellar motor switch proteins FliG, M, N, which were are present.⁶⁰ (Figure 18)

Histidine kinases are proteins that are typically transmembrane enzymes that mediate signal transduction across cellular membranes.⁶⁰ In addition to the previously discussed CheA, there are 45 more genes encoding histidine kinases in BW-2. 3 of these are part of two component response regulator systems.^{60,166,171} BW-2 also has one histidine kinase response regulator. There are two histidine kinase transcriptional regulators specific to the sigma factor 54, which is unlike most prokaryote sigma factors in that it is not related to the more commonly employed sigma 70, indicating these transcriptional regulators may be involved in the initiation of specialized systems.¹⁷² In addition, there are 30 single component, non-histidine kinase response regulator genes in the genome of strain BW-2.

Prophages

While there are several phage and related genes scattered throughout the genome of strain BW-2 including 5 integrases, there are only two regions with clusters that represent nearly complete prophage regions (Figure 23). The first is about 7 Kb in length with a GC percentage of 51.81%. It contains 7 phage associated genes including 3 conserved hypothetical proteins, two phage tail proteins and a conserved phage related protein. The second is about 35.8 Kb with an average GC content of 40.13%, containing 8 phage related proteins.

Figure 23 Prophage Genomic Regions of Strain BW-2

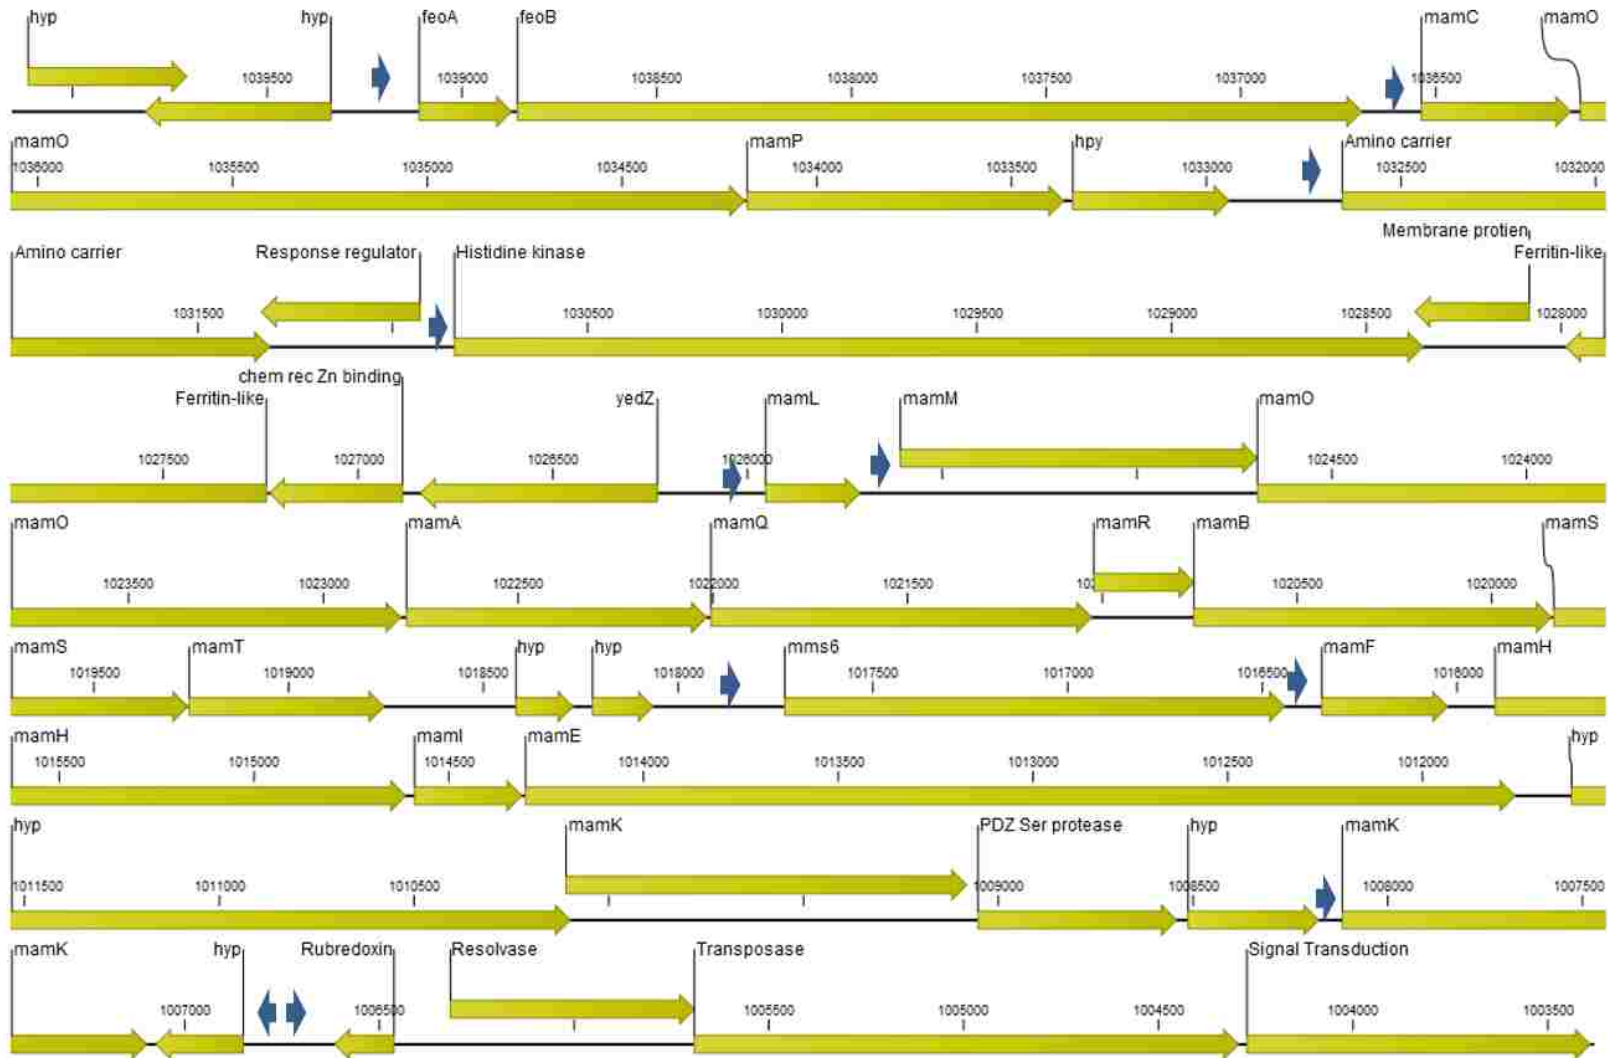

Numbered hash marks indicate genomic position relative to origin of replication as represented by the arrow at noon position. Prophage regions represented by shaded boxes.

Magnetosome Related Genes

An entire set of known magnetosome related genes is arranged in the genome of strain BW-2 as a single contiguous cluster (Figure 24, Table 4). Immediately downstream of this magnetosome gene cluster, are two coding sequences of high homology to a resolvase and a transposase. However, neither the resolvase nor transposase share significant homology to that found in any other strain of MTB. There are no other mobile element proteins or tRNAs in or near the other clusters. Additionally, there is no difference in surrounding region GC

content, and the phylogeny and synteny of the Mam proteins in BW-2 are highly homologous with those in the *Gammaproteobacterium* SS-5. Taken together, this seems to indicate that these genes were not acquired through the result of a recent horizontal gene transfer event, but rather through descent via a last common ancestor shared with SS-5. Further evidence of this is the fact that the majority of magnetosome proteins in BW-2 and SS-5 are most closely related to another unpublished magnetic *Gammaproteobacterium*, strain *Chromatiales* CG-1. The next most related magnetosome associated protein sequences are the corresponding proteins found in the genome of *M. magneticum*, of the *Alphaproteobacteria* (Table 4).

Figure 24 Magnetosome Gene Cluster of Strain BW-2

In BW-2 the upstream end of the magnetosome associated gene cluster consists of the aforementioned *feoA* and *feoB* genes. The *feoA* and *feoB* genes encode a membrane protein FeoA/FeoB, a small soluble protein that is involved in ferrous iron (Fe_2^+) transport in microorganisms.⁸⁹ In most MTB there are at least two clusters *feoAB* type genes, one specific to the MTB (*FeoAB*-like) and another *feoAB* cluster that has the same origin as in other bacteria. However BW-2 has only one set of *feoAB*.⁴²

The *mamCOPD* cluster, which is found apart from the main cluster of magnetotaxis genes in some MTB is upstream and contiguous in this order with the other *mam* genes in BW-2. The gene *mamP* encodes an archetypal MamP protein that comprises one PDZ domain, a conserved domain enabling protein-protein interaction, and two magnetochrome domains.⁶⁶ The gene *mamO* encodes a protein that contains one N-terminus trypsin-like protease domain and one C-terminus TauE domain shown to be involved in the transport of anions across the membrane during taurine metabolism.¹⁷³ The *mamC* gene encodes MamC, an MTB specific protein that does not contain a conserved domain. *mamD* encodes for MamD, a MTB specific protein that also does not contain known conserved domain.

Immediately downstream from the *mamCOPD* cluster is the *mamAB* cluster. This cluster contains two copies of the *mamK* gene, as well as *mam* genes, *L, M, O, A, Q, R, B, S, T, D, F, H, I* and *E* and an *mms6* (Figure 24). This cluster is analogous to the *mamAB* operon described in *Magnetospirillum* species, therefore is referred to as the *mamAB* cluster as there is no evidence whether the genes in this putative operon are also transcribed under the control of a single promoter,^{82,91} and there are in fact 11 identifiable potential promoters within the BW-2 *mamAB* cluster (Figure 24). The *mamAB* cluster is contiguous with the main

magnetosome gene clusters in the genome of strain BW-2 which contains 15 different *mam* genes with *mamI*, *mamE* and *mamK* present as 2 copies. The gene order of *mam* genes in strain BW-2 is generally conserved when compared to the *mamAB* operon of strain SS-5, and *Magnetospirillum* species of the *Alphaproteobacteria*, *Magnetovibrio blakemorei*¹¹⁹ or *Magnetospira* sp. QH-2.¹⁷⁴ Notably, the putative cytoskeletal attachment protein *mamJ*,⁸⁴ once thought to be essential for the construction of the magnetosome chain^{74,82,84} appears to be absent in strain BW-2.

Summary

Taken together, evidence from previous experiments and possible metabolic systems identified in the genome of strain BW-2 described here indicate that this organism has the potential as to fix carbon dioxide autotrophically as well to fix dinitrogen from the atmosphere. In addition, this strain utilizes ammonia as a nitrogen source and respire using reduced sulfur compounds such as sulfide and thiosulfate as electron donors and nitrate and nitric oxide as terminal electron acceptors. 128 established transporters of various types were identified. Few prophage genes were identified and only two clusters that represent near complete prophages. A complement of 21 previously characterized magnetosome-associated genes found in other MTB were identified in the genome of strain BW-2 in a single contiguous cluster without the hallmark features of a genomic island which include the presence of transposase genes, flanking tRNA genes and GC content differing from that of the rest of the genome. The metabolic and magnetosome-related genomic features of BW-2 will be compared with those of

SS-5 and of other MTB in chapter five in the interest of revealing common metabolic features, as of yet uncharacterized genes that may be involved in the magnetotactic phenotype, as well as any evidence of how magnetosome-associated genes are acquired by strain BW-2

Chapter 4 Results from the Genome of Strain SS-5

General genomic features

The SS-5 genome consists of a single circular chromosome of 3,729,439 bp. There is no evidence to indicating the presence of extrachromosomal elements (Figure 25). With an average G+C content of 61.65%, there are 3,724 predicted genes including those encoding 51 tRNAs, 2 sets of 5S/16S/23S rRNAs and 6 miscellaneous RNAs and 1,480 coding sequences of unknown function. The average coding sequence length is 908.25bp with 88.24% of the genome comprised of protein coding genes (Table 5). The *dnaA* gene is immediately followed by an 181 nt intergenic sequence containing two *E. coli* DnaA box sequences with 0 and 1 mismatch, which is immediately upstream of *dnaN*. In addition to a nearby GC skew shift to 0%, this region also contains a 21 bp sequence of 90.3% identity to the probable OriC sequence of strain BW-2, while producing no hits when blasted against NCBI databases (Figure 26). This region was therefore designated the probable OriC¹⁷⁵ and positioned at noon on the circular map.

Figure 25 Circular Genome Map of Strain SS-5

Accession: TBD
Length: 3,729,439

Figure 26 Probable Origin of Replication in the Genome of Strain SS-5

Escherichia coli perfect DnaA box (ttatccaca) was searched for with no more than one mismatch. DnaA boxes underlined and in bold. 21 bp alignment of BW-2 and SS-5 probable OriC sequences is in bold. (2 mismatches at 90.4% identity, no hits when blasted against NCBI)

Strain SS-5 is phylogenetically most closely related to the uncultured, gammaproteobacterial MTB strain CG-1 of the *Chromatiales* order with a 94.93% 16s gene sequence identity. The next most related MTB is the cultured, gammaproteobacterial MTB strain BW-2 described in this work with an 87.58% 16s rRNA gene sequence identity (Figure 16).

Some Important Metabolic Features Based on Genomics of strain SS-5

Autotrophy: CO₂ Fixation

Strain SS-5 has been shown to grow chemolithoautotrophically using sulfide and thiosulfate as electron donors and sodium bicarbonate/CO₂ as the major source of carbon.¹ Coding sequences in SS-5 were identified as form I “green-like” ribulose-1,5-bisphosphate carboxylase/oxygenase (RuBisCO) genes and indicating it has the genetic potential to employ the Calvin-Benson-Bassham cycle for autotrophy.¹ Additionally, the genome of strain SS-5 contains a full set of genes coding for carboxysomes.^{23,32,152–154} As previously discussed, carboxysomes are polyhedral intracellular compartments (Figure 27) known to be involved in

carbon dioxide fixation by enclosing and concentrating RuBisCO, which makes up over 60% of the carboxysome protein.^{32,154} The carboxysome-specific carbonic anhydrase, *csoS3*, likely catalyzes cytoplasmic bicarbonate to CO₂ which is concentrated within the carboxysome and is the main substrate for RuBisCO.¹⁵⁵ This results in the favoring of the carboxylase reaction over the oxygenase reaction leading to the production of glycerate-3-phosphate for use in central carbon metabolism.^{152,153} In all, coding sequences for 38 genes involved in carbon dioxide fixation were identified in the SS-5 genome, including two sets of form I 'green-like' *cbbL* ribulose biphosphate carboxylase (RuBisCO) genes (Figure 28). One set of RuBisCO genes are intact and integrated as part of the upstream end of the α -carboxysomal operon encoded by *csoS2*, *csoS3*, *csoS4A*, *csoS4B*, *csoS1A*, *csoS1B* a bacterioferritin gene, a possible dehydratase and a RuBisCO operon transcriptional regulator gene in the given order. A transposase and a sequence with homology to mobile element associated proteins is 7.9 kb upstream to the long chain *cbbL* gene (RuBisCO large subunit) as well as a tRNA gene, indicating possible rearrangement events mediated by transposase proteins that use tRNA genes as attachment sites.¹⁷⁶ There are also 4 sequences immediately upstream of the RubisCO large subunit gene that are closely related to restriction system genes involved in DNA modification, usually as a defense against exogenously introduced DNA.¹⁷⁷ Among these DNA modifying genes is a gene coding for an abi protein. Little is known about abi proteins except that they are associated with genes which mediate immunity against bacteria derived antibiotics known as bacteriocins.¹⁷⁸ Just over a Mb downstream there is a fragment of the RuBisCO operon adjacent to mobile element, phage and tRNA coding sequences, containing the *cbbL* large chain sequence, the *cbbQ*, *cbbO* and the *cbbR* transcriptional regulator. Another cluster of RuBisCO

genes is in a region roughly 450 Kb downstream that shows signs of previous genomic rearrangement. This incomplete cluster contains the RuBisCO large subunit gene but not the small subunit. Immediately downstream of the large subunit coding sequence there are two genes coding for RuBisCO activation proteins. Another 5.2 Kb downstream is a tRNA and an integrase in another 1.2 Kb. Another Mb downstream there is a third, complete cluster of RuBisCO genes. This region contains the RuBisCO large and small chain *cbbL* sequences upstream of the RuBisCO activation protein genes *cbbQ* and *cbbO*, however there is an intervening 23S rRNA CDS between the *cbbQ* and *cbbO* activation sequences. Immediately upstream of the RuBisCO large subunit there is a tRNA.

Figure 27 Cell Metabolic Overview diagram based on the genomics of strain SS-5

Arrows represent genes, numbered hash marks indicate genomic position in base pairs relative to origin of replication. The genes *csoS2*, *cso4A*, *cso4B*, *csoS1A*, *csoS1B* and *csoS1D* code for carboxysome shell proteins *csoS3* encodes carbonic anhydrase, *hyp* = hypothetical gene

Central carbon metabolism

The gene complement for the TCA cycle is complete in strain SS-5. Genes enabling the TCA cycle to operate in the reductive direction for autotrophy were not found and would be unnecessary in the presence of the complete Calvin-Benson-Bassham cycle. Genes required for carbon flow through glycolysis are present, however the gluconeogenesis doesn't appear to be complete due to a missing fructose-1, 6-bisphosphatase enzyme encoding gene. It may be that this reaction is catalyzed by an unknown nonorthologous enzyme, in that the largest group of confirmed and predicted non-homologous isofunctional enzymes is within carbohydrate metabolism.¹⁵⁶

The acetate transporter acetate permease (*actP*) is present along with all necessary enzymes to convert acetate to acetyl-CoA making it available to the TCA cycle. Previous attempts to grow strain SS-5 heterotrophically on acetate were, however, unsuccessful,¹ indicating this pathway may not be functional or is not so under currently used culture conditions for this strain. Some enzymes for sugar metabolism are present, probably for the resupply of intermediates in anabolic pathways. Consistent with the observed obligate chemolithoautotrophic growth, no identifiable sugar transporters were identified in the genome of strain SS-5.

Iron Metabolism

In that MTB biomineralize iron crystals, cells of MTB contain several orders of magnitude more iron than non-magnetic bacteria. Some strains are known to synthesize up to 16.7 mg magnetite liter⁻¹ day⁻¹.¹⁵⁷ The dry mass of MTB is typically composed of up to 3% iron.¹⁶ Therefore, of obvious importance to MTB is iron metabolism, including its uptake, transport, oxidation and reduction.

The genome of strain SS-5 contains a ferrous iron transport protein coding *FeoB* sequence in addition to multiple copies of the *tonB/exbB/exbD* ferric-siderophore transport complex and a transporter with high homology to iron-chelate binding ATP-binding cassette (ABC) transporters. Two ferric iron uptake regulator protein (*fur*) genes were identified as was a coding sequence for the previously discussed bacterioferritin. Sequences encoding genes involved in Fe²⁺ and Fe³⁺oxidation, detoxification, storage and release regulation¹⁵⁹ were also identified adjacent to the RuBisCO genes. Lastly, as a MTB, strain SS-5 possesses *mamBMEPTH* genes involved in redox control in the synthesis of magnetosome crystals²⁸.

Nitrogen Metabolism

Strain SS-5 is one of the few magnetotactic bacteria that does not demonstrate nitrogenase activity and thus it is not surprising that *nif* genes are not present in the genome of this organism. The strain does utilize ammonia as a source of cellular nitrogen and has an ammonium transporter gene *amt*, glutamine synthetase/glutamate synthase (bacteria-like GS-GOGAT cycle) and glutamate dehydrogenase for the assimilation of ammonia (Figure 27). *NasDE* genes were identified immediately upstream of the nitrite transporter gene *nirC* (Figure 30). The *nasDE* cluster codes for a nitrite reductase that is involved in both assimilatory and dissimilatory pathways and is involved in the reduction of nitrite to ammonia.^{179,180} Assimilatory nitrate reductase genes *nasBC* were not identified. Together, these latter results suggest that strain SS-5 is capable of using nitrite but not nitrate as a source of cellular nitrogen although this remains to be tested in the laboratory.

Denitrification is the sequential dissimilatory reduction of nitrate or nitrite to a gaseous end product (nitrous oxide or dinitrogen) and is a globally important environmental biogeochemical process since it results in the loss of fixed nitrogen from an ecosystem.^{101,121,161} The full pathway of denitrification is shown in Figure 29. Strain SS-5 possesses all the genes for the entire pathway of denitrification¹⁸¹ including those encoding the nitrate reductases NarGHJ, the nitrite reductases NirSK, NasDE and cytochrome cd1, the nitric oxide reductase NorBC, and the nitrous oxide reductase NosZ. (Figure 30). Additionally, the genes encoding the enzymes for the reduction of nitrate to nitrite through a periplasmic respiratory nitrate reductase system,¹²¹ *nap ABCDFGH*, were identified in two gene clusters ~55 Kb apart (Figure

30). However, nitrate transporters have not been identified in SS-5 and despite having these nitrate reducing genes, attempts to grow strain SS-5 anaerobically in the laboratory with nitrate as a terminal electron acceptor were unsuccessful.

Figure 29 The Sequential Reductive Pathway of Denitrification in Prokaryotes Present in Strain SS-5.

Blue boxes indicate nitrogen oxides being reduced (except N_2), teal arrows indicate enzymes mediating the reduction, blue arrows indicate genes for those enzymes present in the genome of strain SS-5.

Figure 30 N Metabolism Gene Clusters in the Genome of Strain SS-5

Arrows indicate genes, numbered hash marks indicate genomic position relative to Ori, Nit = nitrate transporter, Hyp = hypothetical protein, Dnr = Nitric oxide responding transcriptional regulator, yoeB = toxin

Sulfur Metabolism

SS-5 has several genes related to oxidation of sulfide and thiosulfate as sources of high energy electrons to drive respiration. This includes the sulfur oxidation enzymes encoded by *soxAX*, *soxYZ*, *soxB*, the thioredoxin encoding gene *soxW* and the sulfide dehydrogenase encoding gene *soxF*, all in single copies. SS-5 seems to be missing *soxCD*. Sulfur globules have not been observed in SS-5, indicating the sulfur intermediate often seen in thiosulfate-oxidizing bacteria missing *soxCD*^{5,162} is not allowed to accumulate, but is instead immediately further processed. Subsequent oxidation can be achieved by proteins encoded by the reverse-acting (oxidizing) Dsr system that includes proteins closely related to dissimilatory sulfite reductases operating to reduce sulfite.^{5,163} Strain SS-5 has the complete set of 16 Dsr encoding genes including the membrane complex *dsrMKJOP* and the reverse acting dissimilatory sulfite reductase *dsrAB*, as well as *dsrCC4EFHLNRS*.

No genes for sulfate reduction, either assimilatory or dissimilatory, were identified, indicating a reliance on exogenous reduced sulfur sources as a source of cellular S directed to anabolic pathways.

Central phosphate metabolism

Phosphate is often a major growth limiting resource for many microbes in natural habitats and thus many have evolved efficient phosphate acquisition systems. Cells of strain SS-5 produce numerous phosphate inclusions¹ and its genome contains numerous phosphorous metabolism genes. 10 of these are phosphate acquisition system genes, including the *pstSCAB* transporter complex, the PhoR and PhoB two component regulatory system that make up the PHO regulon, in addition to a low affinity inorganic phosphate transporter *lat* and a high affinity *pstABC* ABC transporter. Limiting phosphate conditions lead to the autophosphorylation of the sensory kinase PhoR which activates PhoB by phosphorylation (Figure 22). PhoB is a positive transcription regulator of the *pstSCAB* phosphate regulon that is present in 4 copies in SS-5. In non-phosphate limiting conditions, PhoB may in turn inhibit the kinase activity of PhoR, leading to interaction of PhoR and PhoU to dephosphorylate and inactivate PhoB.^{165,166} SS-5 also has multiple copies encoding an ATPase related to phosphate starvation-inducible protein, PhoH, that may be involved in lipid and phospholipid metabolism and RNA modification.¹⁶⁷ Lastly, there is a *nptA* Na⁺-dependent phosphate transporter gene present in the SS-5 genome. Polymerization of phosphate into the inclusions observed in SS-5 is mediated by the polyphosphate kinase *ppk2*.^{23,32,166,168}

Transporter genes in the genome of strain SS-5

There are 96 membrane transport related coding sequences in the genome of SS-5, in the low range of what is typical of the number expected in an autotrophic prokaryote.^{23,169}

Of these, 6 are ABC transport genes. One gene, *phnD*, is present as a double copy of a phosphate binding periplasmic subunit but without the other components, indicating that either the transporter is incomplete or this protein is part of a non-ABC transporter system. Another two coding sequences are homologous to ABC transporter periplasmic oligopeptide binding subunit OppA and permease OppB that are involved in oligopeptide transport, although the other subunits are missing possibly lost to previous genomic rearrangement events. There is also an incomplete ABC dipeptide transporter, with subunits present for periplasmic dipeptide binding and a subunit for ATP binding but no permease subunit.

There are 19 uni, sym or antiporter genes present in the SS-5 genome. Among these is a Na⁺/H⁺ antiporter, *nhaD* and the aforementioned *nptA* Na⁺ dependent phosphate transporter in two copies. Also present is a complete set of a seven subunit (A-G) Na⁺/H⁺ transporter coding sequences in multiple copies.

38 protein secretion transport related sequences are present in the genome of SS-5. 27 genes are type IV protein encoding genes for pili and fimbriae synthesis, while there are 4 type II protein secretion related proteins, 2 more involved in translocation to the membrane and 3 twin-arginine translocation system genes for export of folded proteins.

There are 8 additional protein encoding genes involved in the transport of cations and 18 more are members of the previously mentioned Ton/Tol transport system.

Additionally, there are 7 Tripartite ATP-independent periplasmic transporter (TRAP) genes, 2 encoding proteins related to C4-dicarboxylate transport. 5 are involved in the transport of as yet unknown substrates, although it is known that they are likely organic acids.¹⁸²

Chemotaxis and signal transduction

There are multiple protein coding sequences for the cyclic second messenger cAMP, genes coding for the cAMP receptor protein FNR, 7 copies of cAMP binding proteins CGA and 7 copies of an adenylate cyclase present in the genome of strain SS-5.

As an aerotactic microbe, strain SS-5 contains genes coding for the O₂-sensitive aerotaxis receptor protein Aer. Genes encoding 21 methyl accepting chemotaxis proteins are also present in multiple copies, including those for Tsr and the methyl transferase CheR. The genes encoding the CheW/CheA/CheY system for signal transduction to the flagellum including CheR and CheB are present in several copies each, ranging from 6 to 9. As previously discussed, the Che system transduces signal to flagellar motor switch proteins FliG, M, N, which are also identified.⁶⁰ 53 genes were identified as encoding proteins with redox sensor PAS/PAC domains along with GGDEF and EAL domains which are involved in the synthesis and phosphorylation of cyclic second messengers like cAMP and cyclic di-GMP.⁶⁰ These proteins react to their redox environment as assessed by their PAS/PAC domains. In this case by synthesis (GGDEF domain) and phosphorylation (EAL domain) of the second messenger cyclic di-GMP.¹⁷⁰

As previously discussed, histidine kinases are proteins that are typically transmembrane enzymes that mediate signal transduction across cellular membranes.⁶⁰ In addition to the previously discussed CheA, there are 26 genes encoding histidine kinases in the genome of SS-5. 2 of these are among the 14 two component response regulators and sensory proteins^{60,166,171} in SS-5. There are also 22 single component, non-histidine kinase response regulators in SS-5.

Prophages

While there are several phage related genes scattered throughout the genome including 45 transposase genes and 24 phage related genes, there does not appear to be a cluster representing a complete prophage.

Magnetosome-Related genes

There are four magnetosome-associated gene clusters in the genome of strain SS-5. The *mamAB* cluster is 29,731 bp, the *mamCOPD* cluster is 5,072 bp, a putative magnetosome associated hypothetical magnetosome protein (*hmp*) gene region is 12,255 bp and a single *feoB*-like gene is in a region of the chromosome not close to any other magnetosome genes (Figure 32, Table 8). Although the majority of the genes putatively involved in magnetosome formation are clustered with the *mamAB* cluster of the SS-5 genome, the smaller *mamCOPD* cluster and three *hmp* genes are located at a different region of its chromosome (Figure 32,

Table 8). These *hmp* genes contain an adenylate cyclase domain and are found only in several MTB, although their role is yet known.

There is no evidence that the magnetosome gene clusters in strain SS-5 represent a genomic island as there are no tRNA or mobile element genes such as resolvases or transposases in or near the magnetosome gene clusters, thus it seems unlikely that the magnetosome genes here originated from lateral gene transfer from another organism. Additionally, there is no difference in surrounding region GC content, and the phylogeny and synteny of the *mam* genes in both strains SS-5 and BW-2 are highly homologous. Taken together, this seems to again indicate that, these genes were not acquired through the result of a recent horizontal gene transfer event, but rather through descent via a last common ancestor of strains SS-5 and BW-2. Further evidence of this is the fact that the majority of magnetosome proteins in BW-2 and SS-5 are most closely related to another unpublished magnetic gammaproteobacterium, strain CG-1 of the order *Chromatiales*. The next most related magnetosome associated gene sequences are the corresponding proteins found in the genome of *M. magneticum*, of the *Alphaproteobacteria* (Table 8).

Figure 31 Magnetosome Gene Clusters in the genome of strain SS-5

As previously discussed, the *feoAB*-like genes encode membrane proteins that are involved in iron transport and appear to be specific to MTB.⁸⁹ In most MTB there are at least two clusters *feoAB*, one specific to the MTB (*feoAB-like* in the magnetotactic *Alphaproteobacteria* and *feoBA-like* in the magnetotactic *Deltaproteobacteria*) and another *feoAB* cluster that has the same origin as in other bacteria.^{33,89} However, in the genome SS-5 there is just one *feoB*. Interestingly, in the genome of SS-5 there is no *feoA* homolog.

An ~5kb *mamCOPD* cluster is present in the genome of strain SS-5 that contains magnetosome genes *mamPOCD* in that order, with an coding sequence between *mamC* and *mamD* that encodes a protein of unknown function that does not share homology with any protein from other bacteria. The gene *mamP* encodes an archetypal MamP protein that comprises one PDZ, a conserved domain enabling protein-protein interaction, and two magnetochrome domains.⁶⁶ The gene *mamO* encodes a protein that contains one N-terminus trypsin-like protease domain and one C-terminus TauE domain. The *mamC* gene encodes MamC, a MTB specific protein that does not contain domains conserved with other bacteria. *mamD* encodes for MamD, an MTB specific protein that does not contain known conserved domains.

There is another copy of *mamD* far from the magnetosome gene clusters, named *mamD-2*, which likely originated from a duplication of *mamD-1* or vice versa. In fact, phylogenetically, the proteins *mamD-1* and *mamD-2* are more closely related to each other than they are to *mamD* from other MTB. Just upstream of this *mamD-2*, there are three uncharacterized genes designated *hmp*. These are highly homologous to genes found in

Magnetospirillum. Interestingly, two of these sequences that have homologs in *Magnetospirillum* are collinear and found in the vicinity of the magnetosome island.

The ~21.8kb SS-5 cluster contains the *mamAB* cluster which includes *mamI*ELMOAQRBSTFHIEKK and an *mms6* gene. There are two copies each of *mamI*, *mamE* and *mamK* (Figure 32). The putative cytoskeletal attachment protein *mamJ*⁸⁴ appears to be absent. As previously discussed, this cluster is analogous to the *mamAB* operon described in *Magnetospirillum* species, and so is referred to it as *mamAB*, although, again, there is no evidence whether the genes in this putative operon are also transcribed under the control of a single promoter. In fact, there are 10 identifiable potential promoters within the *mamAB* cluster of SS-5. (Figure 32)

Summary

Taken together, evidence from previous experiments and the genetic systems identified in the genome of SS-5 here indicate that it has the potential as an autotroph to fix carbon and ammonia from the environment, however, unlike most MTB appears to be unable to fix nitrogen. The ability to respire by oxidizing reduced sulfur compounds such as sulfide and thiosulfate and reducing nitrate and nitric oxide was also indicated. 96 established transporters of various types were identified. Few prophage genes were identified and none clustered as an identifiable prophage. A compliment of 24 previously characterized magnetosome associated genes found in other MTB were identified in strain SS-5 in two clusters separated in the genome but without the hallmark features of a genomic island such as the presence of

transposases, flanking tRNAs and a GC content differing from that of the rest of the genome.

The metabolic and magnetosome related genomic features of BW-2 will be compared with those of BW-2 and of other MTB in chapter five in the interest of uncovering common metabolic features, as of yet uncharacterized genes that may be involved in the magnetic phenotype, as well as any further evidence of the nature of the acquisition by strain SS-5 of these magnetosome related genes.

Chapter 5 Comparative Analysis

Phylogeny

Based on 16S rRNA gene sequence homologies of strains BW-2 and SS-5, these prokaryotes belong clearly to the *Gammaproteobacteria*. Originally strain BW-2 was determined to be in the order *Thiotricales* while SS-5 was placed among members of the *Chromatiales*.¹ Upon subsequent phylogenetic analysis in this work, however, the phylogenetic position of strain BW-2 has been resolved and revised which shows it belongs to the *Chromatiales* rather than the *Thiotricales* (Figure 33).

Figure 32 Phylogenetic tree showing phylogenetic positions of strains BW-2 and SS-5BW-2 and SS-5

Unpublished tree from collaborator on this work, Caroline Monteil. Phylogeny of the *Gammaproteobacteria* class based on 16S rRNA gene sequences. Analysis of the nucleotide sequences of 281 strains largely belonging to the *Thiotrichales* and *Chromatiales*, aligned with MUSCLE¹⁸³, tree constructed with MEGA 7¹⁸⁴ MTB names are in bold, 100 bootstraps were conducted to get proportional support values. Branch lengths represent the number of nucleotide substitutions per site. *Chromatiales* and *Thiotrichales* are colored in red and blue respectively according to the NCBI taxonomy database.

When compared to other MTB, strain BW-2 is most closely phylogenetically related to strain SS-5 with a 16s rRNA gene sequence identity of 87.58% (Figure 16). The next most related magnetotactic strain to BW-2 is the newly isolated and as yet unfinished genome of the gammaproteobacterial, *Chromatiales* strain CG-1. Strains BW-2 and CG-1 share an 85.12% 16s rRNA gene sequence identity. Strain SS-5 is most related to strain CG-1 with 94.93% 16s rRNA gene sequence identity then secondly with BW-2 at 87.58% 16s rRNA gene sequence identity. The next most related MTB to these magnetic *Gammaproteobacteria* is *Magnetococcus marinus* strain MC-1 of the *Alphaproteobacteria*.

Metabolic comparisons

BW-2 and SS-5 share a similar metabolic lifestyle as chemolithoautotrophs, using sulfide and thiosulfate as high energy electron sources, O₂ or possibly certain nitrogen oxides as electron acceptors, and sodium bicarbonate or CO₂ as primary carbon sources.¹

Autotrophy

Both strains have intact genetic systems coding for RuBisCO-mediated CO₂ fixation in two sets. Both are found in the same region in strain BW-2 within 6,382 bases, (Figure 17) while in strain SS-5 one set is in two fragments over a megabase apart and interspersed and flanked with 23S rRNA, tRNA, mobile element and phage protein coding sequences (Figure 28). In each strain, one RuBisCO cluster is incorporated into a carboxysome gene operon while one

is not. Complete carboxysome gene sets are also present in both strains, although carboxysomes or carboxysome-like structures yet to be observed in either strain under currently used culture conditions. While these operons are present in both strains, the synteny of the genes is different possibly due to a rearrangement of genes during their evolutionary divergence.

Many MTB of the *Alphaproteobacteria* also grow chemolithoautotrophically. Genes coding for RubisCO type II have also been identified in *M. gryphiswaldense*, *M. magnetotacticum* and *Magnetovibrio blakemorei*, whereas *Magnetococcus marinus* and strain MO-1 grow chemolithoautotrophically using the reverse tricarboxylic acid cycle. To date, however, carboxysome operons have not been identified in other MTB, and MTB species discovered so far belonging to the *Deltaproteobacteria* are chemoorganoheterotrophs.⁶

Central Carbon Metabolism

Intact TCA cycle and glycolysis gene sets are identifiable in both strains BW-2 and SS-5. However, similarly to *Magnetococcus marinus*, both are missing any known fructose-1,6-bisphosphatase isozyme,¹⁵⁶ an enzyme necessary to the gluconeogenesis pathway of carbohydrate synthesis. *Magnetococcus marinus* has two inositol monophosphatase genes, one of which was determined to be similar to an archaeal fructose-1,6-bisphosphatase gene, possibly performing this function.⁵⁶ BW-2 and SS-5 also have two inositol monophosphatase genes, but neither of them are more similar to archaeal fructose-1, 6-bisphosphatase than to inositol monophosphatase of other bacteria. One explanation for this absence of fructose-1, 6-

bisphosphatase could be that this reaction is catalyzed by unknown nonorthologous enzyme acquired in a common ancestor. In support of this possibility the largest group of confirmed and predicted non-homologous isofunctional enzymes is within carbohydrate metabolism.¹⁵⁶ There are also no identifiable sugar transporters in either strain, consistent with the lack of success in growing these strains heterotrophically. As previously discussed however, the acetate transporter acetate permease (*actP*) is present in both BW-2 and SS-5 along with all necessary enzymes, including acetyl-CoA synthetase, to convert acetate to acetyl-CoA making it available to the TCA cycle.

Nitrogen Metabolism

Both gammaproteobacterial strains can also acquire nitrogen in the form of ammonia from the environment for assimilation into cellular components via an ammonium transporter and the GS-GOGAT cycle to incorporate it into amino acids. In addition *NasDE* genes were identified in strain SS-5 immediately upstream of the nitrite transporter gene *nirC* (Figure 30). The *nasDE* cluster codes for a nitrite reductase that is involved in both assimilatory and dissimilatory pathways and is involved in the reduction of nitrite to ammonia.^{179,180} Assimilatory nitrate reductase genes *nasBC* were not identified. Together this suggests that strain SS-5 is capable of using nitrite but not nitrate as a source of cellular nitrogen although this remains to be tested in the laboratory. BW-2 does not have an assimilatory nitrate reductase but does have a complete nitrogenase system. By contrast, while strain BW-2 does not have an assimilatory nitrate reductase and therefore does not appear to be capable of

using nitrate as a sole source of nitrogen for growth, it does have a complete nitrogenase regulon enabling it to also fix nitrogen from the environment (Figure 19). Both BW-2 and SS-5 appear capable of reducing some nitrogen oxides in a dissimilatory fashion as terminal electron acceptors in lieu of O₂ (Figure 34), however only strain BW-2 appears capable of taking up nitrate via two copies of nitrate/nitrite transporters. No nitrate transporters were identified in strain SS-5. Strain BW-2 has the genes for the enzymes dissimilatory nitrate reductase and nitric oxide reductase, suggesting that this strain has the potential to use nitrate and nitric oxide as terminal electron acceptors in respiration. Strain SS-5 possesses the complete suite of genes encoding the enzymes for the complete pathway of denitrification and thus has the potential to reduce nitrate to dinitrogen gas.

Figure 33 Nitrogen oxide reduction in strains BW-2 and SS-5

Blue boxes indicate nitrogen species being reduced, teal arrows indicate enzymes mediating the reduction, blue arrows indicate genes present in respective strains.

Nitrogenase activity is typically confirmed in MTB including most MTB of the *Alphaproteobacteria* including *M. magneticum*, *M. gryphiswaldense*, *Magnetococcus marinus*,

Magnetovibrio Blakemorei, *Magnetospira thiophila* and most affiliated with the *Deltaproteobacteria*.¹² In fact, dissimilatory nitrate reduction has been functionally linked to nitrogenase activity¹⁸⁵ and to magnetite biomineralization in *M. gryphiswaldense*, and related enzymes participate in redox reactions required for magnetite biomineralization.¹²¹ However, as of yet unidentified enzymes likely perform these functions in *Magnetospira* sp. QH-2 as genes for nitrogenase are absent from its genome.¹⁷⁴ Similarly to BW-2 and SS-5, *Magnetococcus marinus* additionally has the GS-GOGAT cycle and glutamate dehydrogenase for the assimilation of ammonia.

Sulfur Metabolism

Both strains BW-2 and SS-5 are sulfide and thiosulfate-oxidizing bacteria. As such, they have several genes related to sulfur metabolism scattered throughout its genome including the sulfur oxidation (SOX) system and the reverse acting (oxidative^{5,163}) dissimilatory sulfite reductase (Dsr) systems, as previously discussed. While both strains are missing *soxCD*, as is typical of other *Gammaproteobacteria* that oxidize sulfur using the SOX system,⁵ only BW-2 is observed to accumulate sulfur inclusions when cultured with thiosulfate as is observed in many other bacteria that perform SOX reactions without *soxCD*.⁵ Sulfur globules have not been observed in SS-5, indicating the sulfur intermediate often resulting in SOX reactions without *soxCD* is not allowed to accumulate, but is instead immediately further processed by the Dsr system into sulfite, then further oxidized to sulfate by the SOX system.^{5,163}

Genes for dissimilatory sulfate reduction were not identified in either strain.

Assimilatory sulfate reduction genes were also not identified indicating a reliance on exogenous reduced sulfur sources as a source of cellular S directed to anabolic pathways. YedYZ, a putative membrane associated reductase (often annotated as sulfite oxidase) is present in BW-2 and could be active in the reduction of sulfur species as, although its functions are largely unknown it has been shown to act upon sulfur containing substrates.¹⁶⁴ The genome of *Magnetococcus marinus* also encodes YedYZ, however its sulfate assimilation pathway is incomplete with only the first two enzymes present, likely also acquiring reduced sulfur exogenously.⁵⁶ By contrast, the genomes of *M. magneticum* and *M. magnetotacticum* contain all genes necessary for assimilatory sulfate reduction⁵⁶ Although the MTB of the Deltaproteobacteria do reduce sulfate in a dissimilatory fashion, they are chemoorganoheterotrophs.

Sulfur compound oxidation is also typical of other MTB. The two strains of magnetococci in culture, *Magnetococcus marinus*⁵⁶ and strain MO-1,¹² grow chemolithoautotrophically using reduced sulfur compounds as electron donors. *Magnetococcus marinus*, similarly to BW-2 and SS-5, is also missing *soxCD*.⁵⁶ As observed in BW-2, it also produces sulfur globules that accumulate intracellularly that may be further converted to sulfite via its Dsr system. *M. gryphiswaldense* is also capable of autotrophic and mixotrophic growth utilizing reduced sulfur compounds and *Magnetovibrio blakemorei*¹¹¹ grows chemolithoautotrophically with reduced sulfur compounds. *Magnetospira thiophila* (strains MMS-1 and QH-2) grow chemolithoautotrophically using thiosulfate.

Phosphate Metabolism

Both SS-5 and BW-2 produce numerous phosphate inclusions and have numerous phosphorous metabolism genes. In the interest of acquiring phosphate from the environment, BW-2 has 13 phosphate transport system genes while SS-5 has 10. Although each has the same genes present, the SS-5 genome additionally encodes a low affinity inorganic phosphate transporter. Both BW-2 and SS-5 have the PstSCAB transporter complex as well as the PhoR and PhoB two component regulatory system. Limiting phosphate conditions lead to the autophosphorylation of the sensory kinase PhoR which phosphorylates the PhoB positive transcription regulator of the phosphate regulon that is present in multiple copies. In non-phosphate limiting conditions, PhoB can in turn inhibit the kinase activity of PhoR, leading to interaction of PhoR and PhoU to dephosphorylate and inactivate PhoB.^{165,166} Both SS-5 and BW-2 also have multiple copies encoding an ATPase related to phosphate starvation-inducible protein, PhoH, that may be involved in lipid and phospholipid metabolism and RNA modification.¹⁶⁷ Lastly, both genomes encode an nptA Na⁺-dependent phosphate transporter. Unlike SS-5, BW-2 produces phosphate inclusions. Predictably, coding sequences for polyphosphate kinase and exopolyphosphatase, the enzymes involved in the production of phosphate granules, were found in two copies each in BW-2.

Polyphosphate inclusions are commonly found in environmental samples of MBT.¹² These inclusions are also common in cultured MTB, including all three *Magnetospirillum* strains and *Magnetococcus marinus* which also contain genes encoding polyphosphate kinase and exopolyphosphatase.¹⁸⁶

Transport Genes

There are 128 membrane transport related coding sequences in the genome of BW-2, typical of the number expected in an autotrophic prokaryote,^{23,169} and 96 membrane transport related coding sequences in the genome of SS-5, a somewhat low number but still in the low range typical of the number expected in an autotrophic prokaryote.^{23,169} In BW-2, 11 of these are ABC transport genes while in SS-5, 6 are ABC transport genes. In both BW-2 and SS-5 the double copy of the *phnD* phosphate binding periplasmic subunit is present without the other components, indicating that either the transporter is incomplete or this protein is part of a non-ABC transporter system. Another two coding sequences homologous to the ABC transporter involved in oligopeptide transport that was found to be partially present in SS-5 are present in BW-2. In both cases, there are permease subunits *oppB* and *oppC*, and no subunit *oppA*, indicating loss of the other components due to genomic rearrangement in the last common ancestor of the two strains. There is also an incomplete ABC dipeptide transporter in SS-5 that was not identified in BW-2, with subunits present for periplasmic dipeptide binding and a subunit for ATP binding but no permease subunit. In BW-2, a complete set of genes representing a branched chain amino acid ABC transport system, *livFGMHJ* and the high-affinity leucine-specific periplasmic binding protein LivK, were found that were not found in SS-5. There are also 16 uni, sym or antiporters in BW-2 and 19 uni, sym or antiporter genes present in the SS-5 genome. As in SS-5 there is a Na⁺/H⁺ antiporter, *nhaD*, but in three copies instead of the one in SS-5, as well as the *nptA* Na⁺ dependent phosphate transporter in one copy but with three found in SS-5. Additionally, in both BW-2 and SS-5 there is a complete set of a seven subunit (A-G) Na⁺/H⁺ transporter, with five of these in duplicate. There are 74 protein secretion

transport related sequences are present in BW-2 and 38 protein secretion transport related sequences are present in the genome of SS-5. In BW-2, this includes 31 type IV protein encoding genes for pilin and fimbriae synthesis and 27 in SS-5. However, unlike SS-5 that encodes no type I proteins, 31 type I proteins for autoaggregation and biofilm formation are present in BW-2 in multiple copies. In BW-2 there are 20 copies of T1SS secreted agglutinin alone in addition to multiple copies of *lapBCE*. These systems are clearly active when growing BW-2 in sulfide containing medium with a headspace of air, as cells form floating aggregations and adhere to the side of the jar at and near the surface of the liquid phase of the medium (Figure 35). In both strains there are also 4 type II protein secretion genes, 2 more that are involved in translocation to the membrane and twin-arginine translocation system genes for export of folded proteins, 4 in BW-2 and 3 in SS-5. BW-2 has 9 additional protein encoding genes involved in the transport of cations while SS-5 has 8. Both strains have 18 genes that encode members of the previously discussed Ton/Tol transport system. Present in SS-5 but not found in BW-2, are 7 Tripartite ATP-independent periplasmic transporter (TRAP) genes, 2 encoding proteins related to C4-dicarboxylate transport. 5 are involved in the transport of as yet unknown substrates, although it is known that they are likely organic acids.¹⁸²

The 12 and 96 membrane transport related coding sequences found in BW-2 and SS-5 respectively represent a somewhat low number, but still in the typical range expected in an autotrophic prokaryote.^{23,169} Heterotrophic bacteria often have a higher number of transporters as they take up multiple sources of carbon such as sugars, organic acids and amino acids.¹⁶⁹ By comparison, there are 259 in the genomes of *M. magneticum*, 694 in *M. magnetotacticum* and *Magnetococcus marinus* contains 115.⁵⁶ With respect to iron uptake,

MTB have a high demand, engaging in the synthesis of up to 16.7 mg magnetite liter⁻¹ day⁻¹.¹⁵⁷

As previously discussed, MTB have in common the *feoA-like*, *feoB-like*⁸⁹ and *mamN*⁸³ genes involved in iron transport, in addition to the *feoAB* genes that are more widespread among prokaryotes.⁸⁹ The MTB specific genes *mamB* and *mamM* have homology to cation diffusion facilitator family genes⁵⁶ but as they are magnetosome-associated proteins, they are involved in transport of cytoplasmic iron into magnetosome vesicles rather than into the cell.

Figure 34 Growth of strain BW-2 in Sulfide Containing Medium

Strain BW-2 growth in 825 mL sulfide containing medium with a headspace of 175 mL air. White accumulations on and just below the surface are BW-2 cell aggregates.

Chemotaxis and signal transduction

There are multiple protein coding sequences for the versatile cyclic second messenger cAMP signal in BW-2 and SS-5. Both have genes coding for the cAMP receptor protein FNR, multiple copies each of cAMP binding proteins CGA and 14 and 7 copies for BW-2 and SS-5 respectively of an adenylate cyclase. As aerotactic microbes, both SS-5 and BW-2 have the gene coding for the aerotaxis receptor protein Aer. Both genomes also contain many copies of genes coding for methyl accepting chemotaxis proteins. 21 are identified in SS-5 and 35 in BW-2, including genes encoding Tsr and the methyl transferase CheR. The genome of strain BW-2 also contains the gene coding for the CheC inhibitor of methyl accepting chemotaxis **proteins**

as well. Both strains have many copies of genes encoding the CheW/CheA/CheY system for signal transduction to the flagellum including CheR and CheB, with BW-2 additionally encoding the chemotaxis response phosphatase CheZ. The Che system transduces signal to flagellar motor switch proteins FliG, M, N, which are also identified in both strains.⁶⁰ There were also genes identified as encoding proteins with redox sensor PAS/PAC domains along with GGDEF and EAL domains which are involved in the synthesis and phosphorylation of cyclic second messengers. (eg. cAMP) 53 of these were identified in SS-5 and 61 were identified in BW-2 in addition to 2 with the PAS/PAC domain only. Histidine kinases, proteins that are typically transmembrane enzymes that mediate signal transduction across cellular membranes. In addition to the previously discussed CheA, there are also 45 genes encoding histidine kinases in BW-2 and 26 in SS-5. Some of these are part of two component response regulator systems. 2 of these are among the 14 two component response regulators and sensory proteins in SS-5. BW-2 only has 3 two component systems, one response regulator and two sigma 54 specific transcriptional regulators. There are 22 single component, non-histidine kinase response regulators in SS-5 and 30 in BW-2.

As previously discussed, MTB rely upon magnetic orientation coupled with aerotaxis to find the optimal redox conditions or O₂ concentration in a water or sediment column. High numbers of chemotaxis genes would therefore be expected. In total BW-2 has 57 and SS-5 has 53. By comparison *M. magneticum* contains 162 chemotaxis coding sequences, *M. magnetotacticum* contains 326 and *Magnetococcus marinus* contains 65.⁵⁶ Among all motile prokaryotes, the average number of chemotaxis genes per Mb has been roughly estimated to

be 12.2.⁵⁶ As expected, BW-2 and SS-5 contain slightly higher compliment of genes with 14.25 and 14.24 per Mb respectively.

Prophages

Despite the presence of 45 transposase genes and 24 phage-related genes, there are no predicted prophages in the genome of strain SS-5. The genome of strain BW-2 contains two regions containing clusters of phage-related genes that appear to represent incomplete prophages (Figure 23). This is a low number when compared to the genomes of *M. magneticum* which contains 12 putative prophages, *M. gryphiswaldense*, which contains 6 and a plasmid containing 1, and *Magnetococcus marinus* which contains 14.⁵⁶ Therefore it appears unlikely that when undergoing stress, phage genes in these strains could mediate horizontal gene transfer events by becoming activated and encapsulating genes to pass them on to new microbes. Nor does it appear that such an event has recently introduced genes into the genomes of strains BW-2 or SS-5.

Magnetosome genetics comparisons

Gene compliment and synteny

Genes that are involved in the same process or pathway tend to be found clustered in the chromosomes of prokaryotes, which is useful in consolidating support for the inference of the function of putative genes found among them.¹⁸⁷ In the genome of strain BW-2, the

magnetosome genes are arranged as a single contiguous cluster (Figure 36). By contrast, although the majority of the genes putatively involved in magnetosome formation are clustered with the *mamAB* cluster of the SS-5 genome, there is a smaller *mamCOPD* cluster and three putative *hmp* magnetosome-associated genes located at a different region of its chromosome (Figure 36).

Figure 35 Comparison of synteny of Mam gene clusters in strains BW-2 and SS-5

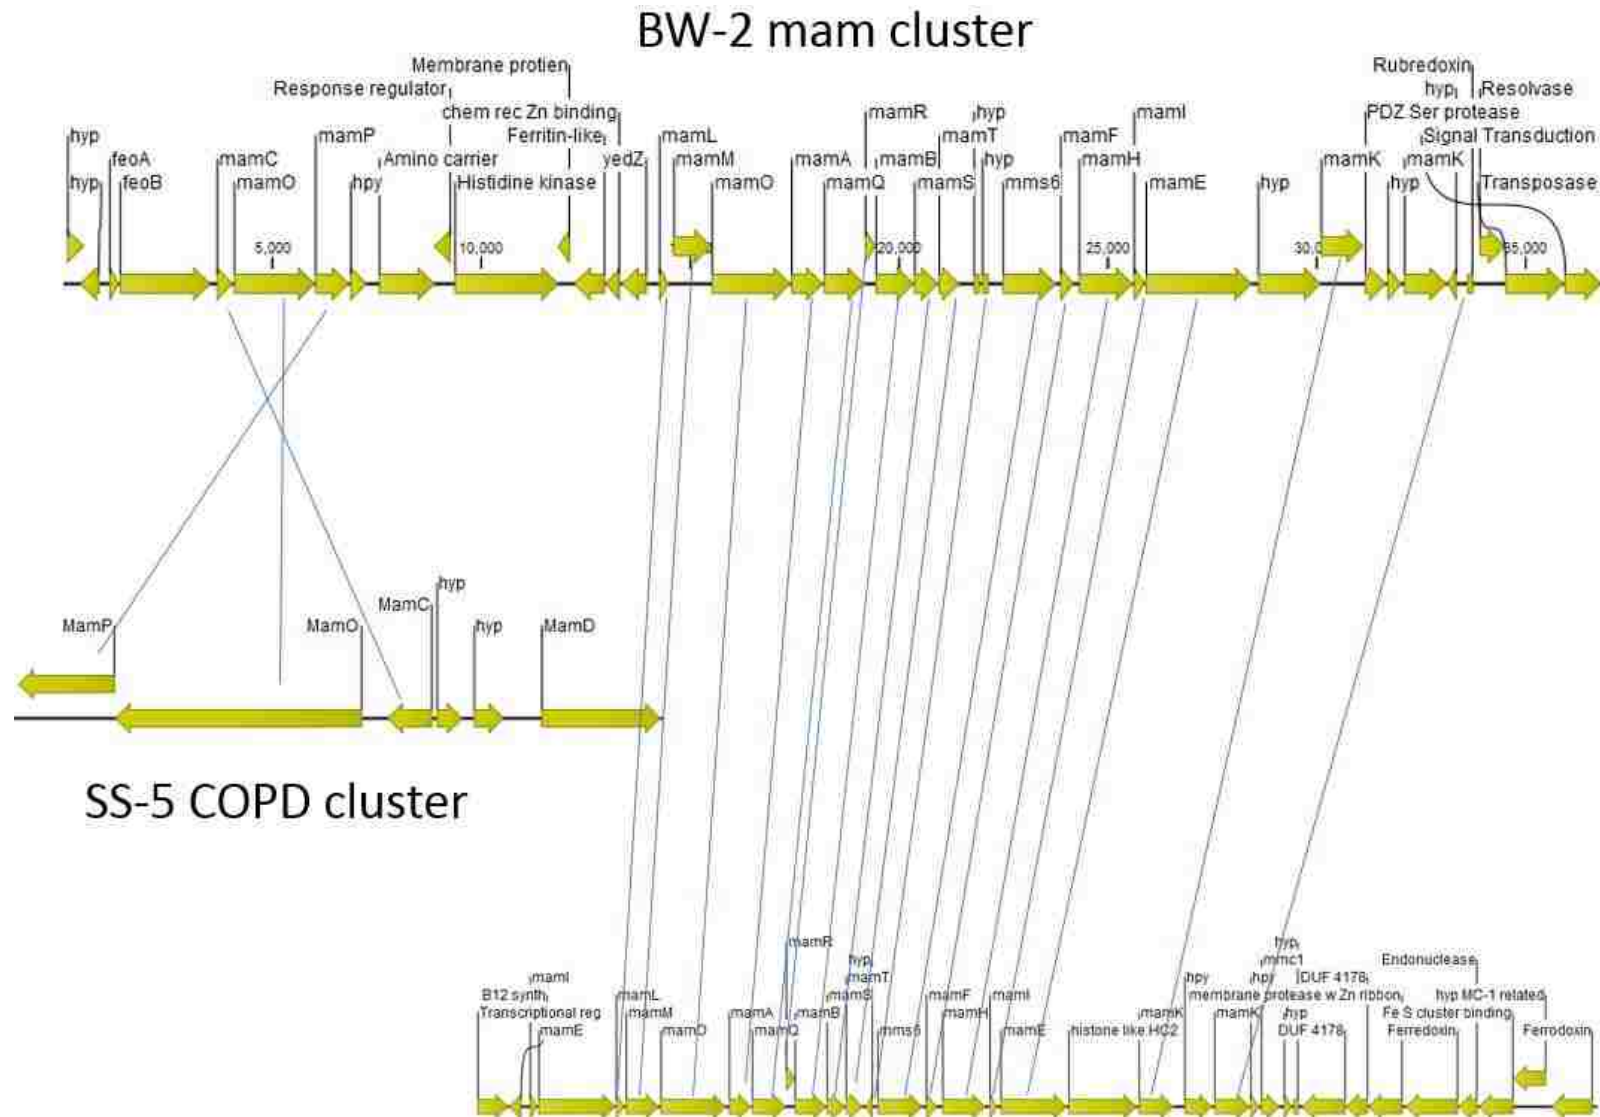

Figure 36 Magnetosome gene Cluster Comparison Across MTB

Black arrows indicate magnetosome genes, gray shapes illustrate crystal morphology and composition, colored fields indicate phylogenetic groups, vertical blue arrow indicates phylogenetic divergence, white boxes indicate genes shared only between MTB of *Gammaproteobacteria* and *Alphaproteobacteria*, bolded boxes indicate gene shared by all MTB of the *Alphaproteobacteria* and *Gammaproteobacteria* exclusively and possible uncharacterized magnetosome genes are indicated by asterisk

The synteny of mam genes in the genomes of strains SS-5 and BW-2 is generally conserved when compared to the *mamAB* operons of MTB of the *Alphaproteobacteria* such as *Magnetospirillum* species, *Magnetovibrio blakemorei*¹¹⁹ or *Magnetospira* sp. QH-2¹⁷⁴ (Figure 37). Some of the differences between SS-5/BW-2 and *Magnetospirillum* species are that *mamN* is absent, *mamK* is positioned at the downstream end of the cluster, and *mamP* is in another cluster containing *mamPO* and *C* in SS-5 while they are present in the order *mamC*, *mamO*, *mamP* at the upstream end in strain BW-2 along with the FeoAB MTB specific Fe transport cluster. Notably, the previously discussed putative cytoskeletal attachment protein *mamJ*⁸⁴ appears to be absent in both strains as is the case with *Magnetovibrio blakemorei*, *Magnetospira* sp. QH-2, and *Magnetococcus marinus*. Strains SS-5 and BW-2 have eighteen magnetosome-associated genes in common only with the different species of the magnetic *Alphaproteobacteria*, which produce clearly faceted, cuboctahedral or elongated prismatic magnetite crystals, but not the MTB of the *Deltaproteobacteria* or *Nitrospirae* (Figure 37). Notably, of these genes, only *mamC* and *mamS* are common to BW-2, SS-5 and each of the MTB from the well characterized magnetotactic *Alphaproteobacteria* (*M. magneticum*, *M. gryphiswaldense*, *M. magnetotacticum*, *Magnetovibrio blakemorei*, *Magnetococcus marinus* and *Magnetospira* sp. QH-2).

Magnetosome gene and morphology phylogeny

When compared to the magnetite-producing magnetotactic *Delta*- and *Alphaproteobacteria*, strains BW-2 and SS-5 share with them 11 homologous genes involved in

magnetosome formation (Figure 37). A phylogeny based on the concatenated protein sequences that are encoded by these genes indicates that their evolution is congruent with the evolution of the 16S rRNA gene through these strains.¹⁰⁰ Therefore, in light of phylogenetic analyses, gene synteny and gene conservation, the molecular mechanisms involved in magnetosome formation in strains BW-2 and SS-5 of the *Gammaproteobacteria* appear to be more related to the magnetosome formation processes of the magnetotactic *Alphaproteobacteria*. This comports with the more similar crystal morphologies between the groups in that they all produce octahedral or elongated octahedral crystals rather than the tooth- or bullet-shaped crystals of other phylogenetic groups of MTB (Figure 37). The most likely mechanism behind the tight crystal morphology control exhibited by the *Alpha*- and *Gammaproteobacteria* is mediated by the genes they have in common that are not found in the bullet- or tooth-shaped magnetite or greigite producers of the *Deltaproteobacteria*. There is evidence from gene deletion studies in the *Magnetospirillum* species of the *Alphaproteobacteria* that some of these genes are in fact involved in control of magnetite crystal morphology.^{66,83} Of the *Alpha*- and *Gammaproteobacteria*-specific *mam* genes, *mamC*, *mamH* and *mamR* deletion results in size defects only. Deletion of *mamS*, *mamX*, *mms6* and *mmsF* however, results in defects in shape as well as size, indicating these genes are likely involved in controlling the observed octahedral magnetite crystal morphology. In particular, the nature of the aforementioned *mamS* commonality to MTB that produce clearly faceted magnetite crystals as well as the fact that deletions of *mamS* have been shown to result in the severe loss of crystal morphology,⁸³ indicate that *mamS* likely plays a prominent role in controlling magnetite crystal morphology during magnetosome biomineralization.

There is no genomic evidence in SS-5 for recent horizontal gene transfer events, although immediately downstream of the BW-2 magnetosome gene cluster there are two coding sequences of high homology to a resolvase and a transposase. However, neither the resolvase nor transposase share significant homology to that found in any other strain of MTB. There are no other mobile element proteins or tRNAs in or near the other clusters. Additionally, there is no difference in surrounding region GC content, and the phylogeny and synteny of the Mam proteins in strains SS-5 and BW-2 are highly homologous (Figure 36). Taken together, this seems to indicate that these genes were not acquired through the result of a recent horizontal gene transfer event, but rather through descent via a last common ancestor. Further evidence of this is the fact that the majority of magnetosome proteins in BW-2 and SS-5 are most closely related to another unpublished magnetic *Gammaproteobacterium*, strain *Chromatiales* CG-1. The next most related magnetosome-associated proteins sequences are the corresponding proteins found in the genome of *M. magneticum* of the *Alphaproteobacteria*. (Table 4, 8 Figure 37).

Potential uncharacterized magnetosome proteins

Genes in BW-2 with homology exclusive to other MTB

Both strains BW-2 and SS-5 contain genes that appear to encode uncharacterized proteins involved in magnetosome formation based on observations related to their homology with genes found in other MTB and their close proximity to other characterized magnetosome

genes. Within the magnetosome gene cluster of strain BW-2 there is a stretch of eight genes between the *mamCOP* cluster and the *mamAB* cluster that contain three genes which share identity and synteny with other MTB (Figure 38). After a hypothetical amino acid carrier protein immediately downstream from *mamP* there is a protein with high homology to the Na⁺/Gly symporter GlyP and proteins of the Na⁺/Ala symporter superfamily. Next, there is a chemotaxis response regulator with high homology to CheY, a protein that transmits chemoreceptor signals to flagellar motor components. The next putative protein contains a histidine kinase domain with multiple sensor domains. Then, a membrane transport protein, a ferritin protein, a chemoreceptor Zn binding protein, and a Yedz heme binding type protein encoding gene.

Figure 37 Uncharacterized Genes of Interest in BW-2 Mam gene

BW-2 magnetosome gene cluster (top) and expanded view of uncharacterized genes of interest within the cluster (bottom)

The amino acid transporter type protein is most highly related to genes found in six other magnetic bacteria and most related to one found in the *Chromatiales* strain CG-1 with an e-value of 2.00E-161, then to *Magnetococcus marinus* with an e-value of 9.00E-143 (Table 11). It is less closely matched to an amino acid symport gene found in strain SS-5 with an e-value of 2.00E-106 with no nearby characterized magnetosome genes. In *Magnetococcus marinus*, the amino acid symport type protein is located within the magnetosome gene cluster immediately downstream of *mamF* and just upstream of *mamH* with two hypothetical coding sequences intervening. It is located with some synteny in *Magnetovibrio blakemorei* immediately downstream from the Fe transporter like cluster *feoAB*-like, which is found in all other MTB to date.³³ It is also upstream of a hypothetical protein with homology to the hypothetical protein immediately upstream of the *feoAB*-like cluster of strain BW-2 (Figure 39).

Table 9 Sequences with Homology to the Uncharacterized Amino Acid Carrier within the Magnetosome Cluster of Strain BW-2

Gene homology	E-val	Identity
<i>Chromatiales</i> CG1	2.00E-161	53%
<i>Magnetococcus marinus</i> Mc-1	9.00E-143	47%
<i>Magnetofaba australis</i> IT-1	7.00E-137	46%

Figure 38 Amino Acid Symporter Synteny Between Strain BW-2 and *Magnetovibrio blakemorei*

Arrows indicate genes and colored arrows indicate genes displaying synteny with the compared strains. Blue lines connect the homologous genes discussed to illustrate synteny.

The histidine kinase just upstream to the amino acid symporter is a complex, multifaceted protein also found in strains CG1 and SS-5 (Table 12). In SS-5 it is in the same orientation and proximity with the adjacent CheY- like protein, although unlike as in BW-2 it is not clustered with known magnetosome genes (Figure 40). The array of homologous domains within this protein include transcriptional regulators, multiple signaling mechanism domains, an ATP binding domain and photo sensors (Table 13). Interestingly, this histidine kinase in SS-5 is followed by a gene containing a BLUF domain protein involved in sensing blue light, although it is not found associated with magnetosome genes.

Table 10 Sequences with Homology to the mam Cluster Associated His Kinase of Strain BW-2

Gene homology	E-val	Identity
<i>Chromatiales</i> CG-1	2.00E-175	57.96
<i>Thiotrichales</i> SS-5	4.00E-167	56.85

Figure 39 Synteny of the mam Cluster Associated His Kinase between Strain BW-2 and Strain SS-5

Arrows indicate genes and colored arrows indicate genes displaying synteny with the compared strains. Blue lines connect the homologous genes discussed to illustrate synteny.

Table 11 Characterized Protein Domains of the mam cluster associated His Kinase in strain BW-2

Domain superfamily	Identified functions
PAS	Bind ligands, and to act as sensors for light and oxygen in signal transduction
GAF_2	Upregulate ATP and GTP conversion to cAMP and cGMP Present in Phytochromes - regulatory photoreceptors FhIA and NifA transcriptional regulators (often for NifA)
HisKA	conserved signaling mechanisms in prokaryotes and eukaryotes
HATPase_c	Histidine kinase-like ATPases, ATP binding
REC	Signal receiver containing a phosphoacceptor site phosphorylated by histidine kinase
Hpt	Signaling through a two part component systems

After the histidine kinase encoding sequence, there is another hypothetical gene unrelated to any currently characterized protein, and then a coding sequence coding for a protein containing a ferritin domain. This coding sequence is unrelated to sequences in non-MTB, and is most related to one found in strain CG-1, and is also found in *Magnetococcus marinus* found between *mamC* and *mamK* (Table 14).

Table 12 Sequences with Homology to the *mam* Cluster Associated Ferritin of Strain BW-2

Organism with gene homology	e-value	Identity
<i>Chromatiales CG-1</i>	5e-60	50.25
<i>Magnetococcus marinus</i>	6e-53	53

There is also an uncharacterized gene that could play a role in magnetosome biomineralization located in the magnetosome gene cluster between the duplicated *mamK* genes of BW-2, a duplication which is also found in several MTB of the *Alphaproteobacteria*, and in the genome of strain SS-5 but present some distance away from other magnetosome genes. This coding sequence encodes a PDZ serine protease domain similar to the previously discussed MamP. There is a 38% identity match with an e value = 3e-09 between the gene in BW-2 and that of SS-5, a 40% match with e value = 6e-08 with a coding sequence in *Magnetospira* sp. QH-2 and a 37% match with e value = 5e-07 with a coding sequence in *M. magneticum* (Table 15).

Table 13 BW-2 mam Cluster Associated Serine Protease Homology

Organism with gene homology	E-val	% Identity
SS-5	3e-09	38
<i>Magnetospira</i> sp. QH-2	6e-08	40
<i>Magnetospirillum magneticum</i>	5e-07	37

Genes in SS-5 with homology exclusive to other MTB

There is also the second gene immediately following the second *mamK* of SS-5 with homology to one in the *Chromatiales* strain CG-1, one in *Magnetospira* sp. QH-2 and two found in *Magnetococcus marinus* (Table 16). In *Magnetococcus marinus*, QH-2 and CG-1 these are not associated with magnetosome genes and this coding sequence does not contain sequence homologous to a currently characterized protein domain.

Table 14 SS-5 Genes with Homology to the Uncharacterized Gene Following *mamK* in the *mam* Cluster of Strain SS-5

Organism with gene homology	E-val	% Identity
<i>Chromatiales</i> CG-1	3.00E-95	76.27
<i>Magnetospira</i> QH-2	3.00E-53	48
<i>Magnetococcus marinus</i>	9.00E-17	33
<i>Magnetococcus marinus</i>	1.00E-12	34

As previously stated, SS-5 has three hypothetical magnetosome protein encoding genes based on conservation in other magnetotactic species designated *hmp2*, *hmp3* and *hmp4*. These genes have similar localization and organization with homologous genes in other MTB with sequences in National Center for Biotechnology Information (NCBI) database (Tables 17-19). They are clustered in SS-5 with a *mamD* gene away from the *mamAB* or *mamCOPD* clusters. This arrangement is conserved with the arrangement found in the unfinished *gammaproteobacterium* of the *Chromatiales* designated as CG-1 (Figure 41). *hmp2* contains a region that codes for an adenylate cyclase domain, whereas *hmp3* and *hmp4* have no known protein domain coding homology. *hmp2* and *hmp3* are additionally highly homologous with uncharacterized genes in other MTB of the *Alphaproteobacteria* with sequence stored in the European Molecular Biology Laboratory database (EMBL) TrEMBL that do not share similar synteny (Tables 20,21).

There are hypothetical proteins interspersed with these SS-5 and CG-1 *hmp* clusters that are not significantly similar in sequence to those of non MTB species. The arrangement of this cluster is also conserved between SS-5, CG-1 and the unfinished *Magnetospirillum* strain SO-1, but with SO-1 limited to *hmp3*, *hmp4* and *mamD*. Another notable difference is that the SO-1 cluster is immediately flanked on either side by four phage proteins, indicating this strain may have acquired this cluster through a more recent horizontal gene transfer event (Figure 42). When compared with *M. magneticum*, the synteny is again conserved with that of SS-5, CG-1 and SO-1, and again this cluster is flanked by an integrase and a transposase, but limited to *hmp3* and *hmp4* (Figure 43). Synteny of the *hmp/mamD* cluster is conserved not only between SS-5, CG-1, SO-1, *M. magneticum* but with *M. magnetotacticum* as well, again with three phage proteins similar in type to those found flanking the same cluster of SO-1 (Figure 44). Yet again, this cluster arrangement is also observed in the unfinished *M. moscoviense* strain BB-1. In this instance, rather than flanked by phage proteins, the cluster is adjacent upstream to a *mamM* fragment, *mamO* and *mamB* (Figure 45). Finally, this synteny is yet again conserved between SS-5 and the unfinished *M. marisnigri* strain SP-1. *M. marisnigri* has the *hmp3*, *hmp4* and *mamD* genes, but they are accompanied by *mamC* immediately upstream of *mamD* and flanked by a mobile element protein and a virulence protein on the other side of the cluster (Figure 46). The fact that this cluster is so highly conserved in gene complement and synteny across only species of MTB and flanked with magnetosome genes in three of them seems to indicate a potential role in the magnetic phenotype. That phage genes flank this cluster for four of these species indicates potential genomic rearrangement of this cluster and conceivably horizontal

gene transfer. Adding to this possibility is the fact that this cluster is found in MTB across phylogenetic groups, but not in all MTB members of those groups.

Notably, although they are not found in the *Gammaproteobacteria*, there are eight additional hypothetical proteins of interest between *mamC* and the *hmp* genes of this cluster as found in *M. marisnigri*. These genes could be involved in magnetosome formation in the *Alphaproteobacteria* as they are highly conserved in sequence similarity among *Magnetospirillum* species, but not found in other species (Figure 46, Tables 22-29).

Upon finishing the genome of *M. marisnigri* it will be possible to investigate further whether there are additional genes shared by other MTB in this vicinity.

Although such preliminary evidence of potentially uncharacterized magnetosome genes is of interest, functional studies would of course need to be performed to confirm these observations. While these studies would be difficult to conduct in the *Gammaproteobacteria* as there is yet no established genetic system, this could be explored further in the case of the eight genes noted above that were identified in the *Magnetospirillum* as there are tractable genetic systems in place for the *Magnetospirillum*.

As previously stated, the evidence gathered here supports the likelihood that the magnetic phenotype was acquired by descent in the currently known *Gammaproteobacteria* in that only traces of evidence for the magnetosome genes of either BW-2 or SS-5 having ever been associated with a genomic island capable of mediating horizontal gene transfer are detectable. The resolvase and transposase coding sequences at one end of the magnetosome gene cluster of BW-2 also don't share homology to resolvase and transposase genes of known magnetic bacteria. Additionally, the homology of most of the characterized magnetosome genes generally correlate to the phylogeny of the bacterium in which they are found. The yet

uncharacterized genes found among the magnetosome genes of BW-2 and SS-5 appear to be exceptions, though, in that they share sequence identity with magnetic bacteria they are not most closely related to in terms of genome phylogeny. One explanation for this could be that those not shared between BW-2 and SS-5 were lost from one or the other during rearrangement events that led to the lack of synteny in these areas.

Chapter 6 Conclusion

In conclusion, the genomes of strains BW-2 and SS-5, the first two discovered magnetotactic bacteria (MTB) belonging to the *Gammaproteobacteria*, were sequenced, sealed, annotated and compared to one another and to MTB of other phylogenetic groups. Specific goals were to determine the metabolic potential of these two strains as well as the compliment, synteny, origin and evolution of the magnetosome genes, whether there may be sequences that can be identifiable as potentially novel magnetosome associated genes and whether there are genes conspicuously associated with the octahedral magnetosome crystal morphology.

As to general metabolism, the genomes of both MTB strains contain the genes necessary for the utilization of the Calvin-Benson-Bassham cycle for autotrophy and carboxysome formation as well as the genes necessary for the oxidation of reduced sulfur compounds as a source of electrons and nitrogen fixation and dissimilatory nitrogen oxide reduction. This is consistent with their ability to grow as microaerophilic chemolithoautotrophs using thiosulfate and sulfide as electron donors.

Characterized magnetosome genes form a single cluster about 2.3 kb in length in the genome of strain BW-2 while magnetosome genes make up two clusters of about 21.8 and 5 kb in length in the genome of strain SS-5. The gene compliment and synteny of these strains is more closely conserved with one another, then with the octahedral magnetite producers of the *Alphaproteobacteria*, mirroring the phylogeny of the rest of their genomes and indicating the phenotype was likely acquired by descent. Interspersed among the magnetosome genes of

both MTB strains are unique coding sequences that share high homology to uncharacterized, hypothetical magnetosome-associated genes of other MTB. Some of these sequences are associated with uncharacterized coding sequences in MTB of *Alphaproteobacteria* that are highly homologous with one another, only found in these MTB and are similarly organized.

The highly conserved in gene complement and synteny of this cluster across only species of MTB, flanked with magnetosome genes in three of them seems to indicate a potential role in the magnetic phenotype. In four of these species phage genes flank this cluster and it is found in MTB across phylogenetic groups, but not in all MTB members of those groups. This indicates the potential genomic rearrangement of this cluster independently of the characterized magnetosome gene clusters and conceivably horizontal gene transfer.

Further characterization of these newly identified hypothetical magnetosome genes would require the establishment of a genetic system for experimentally derived generation of data. While significant progress was made during this study in the refinement of culturing technique resulting in the robust growth in strain BW-2, a genetic system is not yet in place for the MTB of the *Gammaproteobacteria*. There are, however, established genetic systems in place for *M. magneticum* and *M. magnetotacticum* of the *Alphaproteobacteria* in which novel hypothetical magnetosome genes were identified, presenting the immediate opportunity for further investigation.

Appendix

Table 28 Magnetosome Associated Genes and Functions

Protein	Localization	Process	Function	Deletion Effects
MamA	Cytosol, Dynamic, surrounding vesicles	Invagination of cell membrane	It has multiple domains with TPR motifs (protein-protein interactions); may act as multi-protein assembly site; stabilizes magnetosome chain.	Invagination is not affected. Reduction in the number of magnetosomes and changes in iron accumulation.
MamB	Transmembrane in MM	Iron transport and magnetite nucleation	May be involved in iron transport since has homology to CDF (cation diffusion facilitator). Contains TPR domain (protein-protein interactions) and interacts with MamE; requires MamM for stabilization.	Loss of magnetosome vesicles and of crystal formation.
MamC	Transmembrane in MM	Crystal shape and size	Its loop interacts with magnetosome crystal. It is not essential to biomineralization but may control chemical conditions inside vesicles.	Changes in size and organization of chains and size of vesicles. No effects observed in crystal size or shape.
MamD	Transmembrane in MM, N-terminal in ML	Crystal shape and size	Associated with control over size of magnetosome crystal.	Changes in crystal size.
MamE	Transmembrane in MM, C-terminal towards ML	Iron transport and nucleation	Acts as a serine protease and has PDZ domain (protein-protein interaction) which interacts with MamB and I. Magnetochrome might control the magnetosome redox state and balance between Fe ²⁺ /Fe ³⁺ .	Formation of empty magnetosome vesicles, loss of magnetite synthesis, mislocation of MamI and other Mam proteins.
MamF	Transmembrane MM	Crystal shape and size	Associated to control of magnetosome size; interacts with crystal.	Changes in crystal size.
MamG	Transmembrane in MM	Crystal shape and size	Associated to control of magnetosome size.	Changes in crystal size.
MamH	Transmembrane in MM	Iron transport and nucleation	Contains conserved domains homologous to MFS proteins (membrane transporters) and might function as phosphate transporter during magnetite biomineralization.	Reduced number and size of magnetosomes.
MamI	Transmembrane in MM	Invagination	Involved in the formation and bending of the MM.	Absence of MM.
MamJ	Cytosol	Arrangement of chains	Acts as an anchor between MamK filaments and vesicle membrane to arrange magnetosomes in a chain.	Magnetosomes arranged in clusters and no longer in chains. Reduced magnetotactic response.
MamK	Cytosol	Arrangement of chains	Controls chain assembly and position along the cell axis; positions chain for cellular division; homologous to MreB (actin-like).	Lack of filaments near the magnetosomes. Shorter chains and wrong position of MamJ.
MamL	Transmembrane in MM	Invagination	Involved in the formation of MM; similar to MamI.	Absence of MM.
MamM	Transmembrane in MM	Iron transport and magnetite nucleation	Involved in iron transport and may use H ⁺ /cation antiporter mechanism. Involved in the beginning of crystalization and localization of other Mam proteins; stabilizes MamB; homologous to CDF (cation diffusion facilitator).	Loss of magnetite crystals, formation of empty vesicles.

MamN	Transmembrane in MM	Iron transport and magnetite nucleation	Homologous to Na ⁺ /H ⁺ antiporter and might be involved in the extrusion of H ⁺ from the vesicle.	Formation of empty magnetosome vesicles. Does not affect localization of other proteins.
MamO	Transmembrane in MM; C-terminal in ML	Iron transport and magnetite nucleation	Composed of two domains: (1) transmembrane, homologous to proteins involved in transport of anions across cell membrane and (2) similar to a trypsin-like peptidase, but possibly with no protease function.	Formation of empty magnetosome vesicles.
MamP	Transmembrane in MM with active sites towards ML	Iron transport and magnetite nucleation	Involved in control of crystal number and size and in electron transfer necessary to magnetosome assembly and magnetite formation; similar to MamE and MamT; may contain an iron-binding site.	Defects in crystal size, fewer magnetosomes per cell.
MamQ	Transmembrane in MM; C-terminal in ML	Invagination	Unknown function; homologous to LemA.	Complete loss of magnetosome formation in AMB-1.
MamR	Cytosol	Crystal shape and size	Controls the number and size of crystals; predicted to have a DNA-binding domain.	Smaller magnetosome and weaker magnetotactic response.
MamS	Transmembrane in MM; C-terminal in ML	Crystal shape and size	Controls the number and size of crystals.	Defects in crystal size and morphology, weaker magnetotactic response.
MamT	Transmembrane in MM; C-terminal in ML	Iron transport and magnetite nucleation	Involved in regulation of crystal size and morphology; has a magnetochrome domain.	Defects in crystal maturation and loss of magnetotactic response.
MamU	Cytosol	Invagination	Unknown function. Homologous to DGK Family, that includes kinase involved in regulation of cell response.	None observed.
MamV	Transmembrane in MM	Iron transport and magnetite nucleation	Putative CDF transporter.	None observed.
MamW	MM (structure unknown)	Iron transport and magnetite nucleation	Implicated in magnetite synthesis or not associated to magnetosomes.	None observed.
MamX	Transmembrane in MM; C-terminal in ML	Iron transport and magnetite nucleation	Involved in electron transport, with Cytochrome c-like domain; weak similarity to MamS and E.	Smaller crystals and with irregular shapes. Weaker magnetotactic cell response.
MamY	Transmembrane in MM; C-terminal in cytosol	Invagination	Constricts the MM and consequently affects crystal growth; homologous to BAR proteins (involved in membrane dynamics).	Enlarged magnetosome vesicles with smaller crystals.
MamZ	Transmembrane in MM; C-terminal in ML	Iron transport and magnetite nucleation	Involved in redox control for magnetosome formation; creates an iron oxidoreductase and transport complex with MamX and MamH.	Smaller size of crystals and higher proportion of twinned crystals.
Mms6	Transmembrane in MM	Crystal shape and size	Involved in the initiation of magnetite synthesis and control of crystal shape; presents <i>in vitro</i> activity.	Smaller magnetosomes with heterogeneous shapes. Irregular alignment of chains.
MmsF	Transmembrane in MM	Crystal shape and size	Involved in the control of size and shape of magnetite crystal during maturation.	Formation of elongated crystals and of non-magnetotactic cells.

Magnetosome genes and functions as determined by knock-out experiments in *M. gryphiswaldense*. BAR = Bin/Amphiphysin/Rvs domain related to membrane dynamics; CDF = cation diffusion facilitator; DGK = diacylglycerol kinase; MM = magnetosome membrane associated; ML = magnetosome lumen associated; PDZ = conserved domain enabling protein-protein interaction; MFS = major facilitator superfamily of transporters; TPR = Tetratricopeptide repeat domain enabling protein-protein interactions. Curriculum Vitae

University of Nevada, Las Vegas
4505 S. Maryland Pkwy.
Las Vegas, NV 89154

Email: CoreyGeurink@gmail.com
<https://www.linkedin.com/in/coreygeurink>

EDUCATION:

- Ph.D. Cell and Molecular Biology, University of Nevada Las Vegas 2011-2017
“Genomic Characterization of Magnetic *Gammaproteobacteria* Strain BW-2”
- B.S. Biology, Grand Valley State University 1998-2000

WORK EXPERIENCE:

- Research Assistant, University of Nevada Las Vegas 2011-2017
- Genomic characterization and molecular mechanisms of magnetosome formation in bacteria
 - Next Gen Sequencing and analysis
 - Genome annotation, scaffolding, finishing
 - Teaching and development of undergraduate courses (Biology, Anatomy and Physiology)
 - Lab manager (logistics, purchasing, 14 undergraduate students)
 - Research Experiences for Undergraduates (REU) Mentor
 - Preparation of manuscripts, presentations at meetings, guest lectures
- Supervisor: Prof. Dennis Bazylinski, Las Vegas, NV; Phone: 702-895-2053
- Part Time Instructor, Nevada State College 2015-present
- BIOL 189 Fundamentals of Life Science (lecture and lab)
- Mental Health Technician, State of Nevada – Desert Willow Treatment Centre 2003-2011
- Training and supervising new hires
 - Teaching, leading patient group therapy
 - HIPPA, patient rights
 - Documentation, chart audits
 - Physical management and de-escalation techniques

- Infection control procedures
- Behavior modification techniques

Supervisor: Linda Boyd, RN, Las Vegas, NV; Phone: 702-489-8900

Reason for leaving: UNLV PhD program

Commercial fisherman, Fields and Sons, Kodiak, AK 2002-2002

- All duties related to operation including daily interaction with , handling of all varieties of ocean life

Supervisor: Wallace Fields, Kodiak, AK; Phone: 907-486-8370

Reason for leaving: Salmon season ended

QA In Process Chemistry Lab, Mead Johnson Pharmaceuticals 2001-2002

- Chemical analysis of raw materials, in process and finished product

Supervisor: Marcia Kuipers, Zeeland, Mi; Phone: 616-748 - 7100

Reason for leaving: Temporary employment

SCIENTIFIC SKILLS:

General chemical and microbiological techniques:

- Isolation from various environments, enrichment, identification, culturing of fastidious microaerophilic and anaerobic bacteria
- Transformation, conjugation, cloning
- Preparation of standard, microaerophilic and anaerobic custom medium

Molecular techniques:

- DNA isolation, purification, quantification, gel electrophoresis,
- Extensive PCR techniques (including multiplex, universal primer/dual universal primer-multiplex, vectorette, single stranded, asymmetrical, transposome mediated dual universal primer multiplex and long PCR)
- Cloning, transformation
- Restriction, ligation

Genome sequencing:

- Isolation of bacterial DNA from difficult samples, sequencing and data analysis (Sanger, Illumina, 454, PacBio)
- Genome assembly and scaffolding
- Automated and manual annotation of bacterial genomes
- Bioinformatic interpretation of metabolic pathways

Microscopy techniques:

- Light, confocal, fluorescence

Laboratory management:

- Procurement, implementing Health and Safety policies
- Management of 14 undergraduate research assistants
- Hazardous waste disposal
- Lab equipment setup, calibration, maintenance

Bioinformatics Skills:

- Sequence analysis software (CLC Genomics Workbench, Artemis, Geneious, Clustal, MAUVE, BLAST)
- Genome assembly, scaffolding and annotation software (CLC Genomics Workbench, Geneious, SPAdes, Velvet, BLAST, RAST, MaGe, Artemis, OrthoVenn, DNA plotter, CG view, etc.)

TEACHING EXPERIENCE:

- | | |
|-------------------------------------------------------------------------------|----------------------|
| Part Time Instructor, Nevada State College | Fall 2015-present |
| ▪ BIOL 189 Fundamentals of Life Science (7 sections lecture and lab) | |
| Lab Instructor, University of Nevada – Las Vegas | Sum 2011-summer 2016 |
| ▪ BIOL 189 (14 sections) | |
| ▪ 224 Anatomy and Physiology (6 sections) | |
| Guest lecturer, University of Nevada – Las Vegas | Spring 2013 and 2014 |
| ▪ BIOL 418/618 Microbial Ecology | |
| REU Mentor, University of Nevada – Las Vegas | Sum 2014 |
| ▪ Microbiology Research Experience for Undergraduates | |
| Guest lecturer, University of Nevada – Las Vegas | Spring 2013 |
| ▪ BIOL 478/730 Cancer Cell Biology | |
| Conference Speaker, American Society for Microbiology | Spring 2014 |
| “Genomic Characterization of Magnetic <i>Gammaproteobacteria</i> Strain BW-2” | |
| Graduate Seminar, University of Nevada – Las Vegas | Fall 2011-Spr 2013 |
| ▪ Magnetotactic bacteria | |
| ▪ Molecular evolution | |
| ▪ Genomics | |
| ▪ Alternative splicing | |
| ▪ Autophagy | |
| ▪ Epigenetics | |
| ▪ Neurodegeneration | |
| ▪ Cell physiology of hibernation and caloric restriction | |

PUBLICATIONS:

Culture-independent characterization of novel psychrophilic magnetotactic cocci from Antarctic marine sediments (2016) Abreu F, Araujo AC, Leão P, Silva KT, Marques de Carvalho F, de Lima Cunha O, Almeida LG, Geurink C, Farina M, Rodelli D, Jovane L, Pellizari VH, de Vasconcelos AT, Bazylnski DA, Lins U *Environ Microbiol.* (2016) doi: 10.1111/1462-2920.13388

Draft Genome Sequence of the Obligately Alkaliphilic Sulfate-Reducing Bacterium *Desulfonatronum thiodismutans* Strain MLF1 (2014) Trubitsyn D, Geurink C, Pikuta E, Lefèvre CT, McShan WM, Gillaspay AF, Bazylnski DA. *Genome announcements*, doi: 10.1128/genomeA.00741-14
