## ACKNOWLEDGMENTS

I would like to convey my deepest gratitude to my advisor, Dr. M. Kathryn Iovine, who has been a constant inspiration throughout my PhD period. Her vibrating personality has been of great help both professionally and personally. In her busy schedule she always made time to discuss my research and made me feel hopeful every time my experiment didn't work. Her motivation and guidance throughout my PhD period has enriched my research intellect and made me a better researcher. The 6 years in Lehigh University has been an extremely memorable journey of my life for which I am thankful to many people.

I extend my gratitude to my co-advisor Dr. Robert V. Skibbens, who has helped me tremendously in shaping up my research work. His faith in me along with his valuable guidance was absolutely necessary for building my confidence in my work. I am truly blessed to be having two outstanding advisors and feel grateful to work with them. I am also thankful to both of them for spending numerous hours on critical discussions and editing manuscripts. It has truly been a productive and memorable experience.

I would like to thank rest of my committee members, Dr. Linda Lowe-Krentz and Dr. Robert A. Cornell for taking out time for critical discussions and valuable suggestions in spite of their busy schedule. Their comments were helpful in making my research work strong.

I appreciate the support and technical training given to me by former Iovine lab members- Dr. Quinh Ton, Dr. Joyita Bhadra and Dr. Jayalakshmi Govindan. I am grateful to my friend, Jayalakshmi for her critical comments and scientific advice. I am also very thankful to our lab manager, Rebecca Bowman, without whom it wouldn't be

so easy to do my experiments. My PhD journey has been memorable because I was a part of a fantastic and helpful department. I would like to thank all the members of the Biological Science department- faculty, graduate students and office staff for making my journey great.

Lastly, I would like to express my deepest gratitude to my family for all the support. My husband, Dr. Soutir Bandyopadhyay has always motivated and supported me to fulfill my dreams. Without his support I wouldn't have completed my PhD work. He has spent long hours taking care of our daughter, Anushka, which gave me more time to complete my studies and research work. I am equally grateful to my parents and in-laws for having faith in me and motivating me from long distance. Thank you.

Tg-	Transgene negative
TdT	Terminal deoxynucleotidyl transferase
UTR	Untranslated region
UN	Uninjected
V	Volts
WT	Wild type

## ABSTRACT

Roberts syndrome (RBS) is a human developmental disorder characterized by craniofacial abnormalities, limb malformation and often severe mental retardation. RBS arises from mutations in the cohesin auxiliary factor *ESCO2* that targets the SMC3 subunit of the cohesin complex. Mutations in cohesin subunits and a subset of cohesin auxiliary factors gives rise to a related developmental malady termed Cornelia de Lange Syndrome (CdLS). They are collectively termed cohesinopathies since both disorders comprise overlapping phenotypes and the causative genes for both syndromes perform common activities. The underlying cause of CdLS is largely modeled as occurring through transcriptional deregulation. Whereas, the mechanism that underlies RBS, remains unknown. A popular model states that RBS arises due to mitotic failure that leads to elevated levels of apoptosis. My thesis is based on developing a new vertebrate model system for examining RBS-like skeletal defects in order to better understand the mechanisms underlying the disease. Using the zebrafish regenerating fin model, I discovered a transcriptional role of *esco2* during fin regeneration. First, my results show that *Esco2* contributes to skeletal growth and patterning independent of elevated levels of apoptosis – negating a model for mitotic failure. Second, I provide the first characterization of *Esco2*-dependent gene expression of a skeletal gene, *cx43*, which encodes the gap junction connexin subunit required for cell-cell communication and skeletal development in all vertebrates. Mutations in human *CX43* gives rise to a skeletal disorder, Oculodentodigital dysplasia (ODDD). My results conceptually link ODDD to cohesinopathies and provide evidence that *ESCO2* may play a transcriptional role critical for human development. I next addressed the mechanism through which *Esco2* regulates

*cx43* expression, focusing on the *Esco2* target *Smc3*. My results show that the *Smc3* knockdown perturbs bone and tissue growth that recapitulates RBS-type phenotypes in the regenerating fin model. Importantly, *Smc3* regulates *cx43* expression, similar to that of *Esco2*. Moreover, Chromatin Immunoprecipitation (ChIP) assays revealed that *Smc3* binds to a discrete region of the *cx43* promoter, suggesting that *Esco2* exerts transcriptional regulation of *cx43* through modification of *Smc3* bound to the *cx43* promoter. These findings unify RBS and CdLS as transcription-based mechanisms.

## **CHAPTER 1**

### **Introduction**

## 1.1 The Cohesin ring complex and its auxiliary factors

The fundamental component of many cellular processes is the tethering together of two DNA segments, either in *cis* (intramolecular) or *trans* (intermolecular) conformations (Zakari et al., 2015; Skibbens, 2016). For instance, DNA segment *trans*-tethers between two separate DNA molecules, such as sister chromatids, identify the products of chromosome replication as sisters from S phase until anaphase onset. In addition to ensuring high fidelity chromosome segregation, *trans* tethers ensure proximity of template DNA required for error-free DNA repair events. On the other hand, *cis*-DNA tethering occur at the base of a single DNA molecule forming looped structures that brings into registration regulatory elements such as enhancers, promoters, insulators, terminators, etc. that deploy developmental transcription programs largely thought to occur during the G1 stage of the cell cycle. DNA segment *cis*-tethers also promote longitudinal compaction of DNA molecules that is required for regional changes in chromatin structure during G1 and genome-wide chromosome condensation during mitosis. Interestingly, a single complex that participates in various essential cellular activities via both *cis* and *trans*-DNA-tethering conformations is the multi-subunit cohesin complex and along with its auxiliary factors (Figure 1.1).

Cell division is a fundamental process by which cells replicate and generate identical daughter cells. The process of cells duplicating themselves starts with the S phase in which each parent cell replicates its chromosomes and ends with Mitosis in which sister chromatids segregate into newly formed daughter cells. For proper functioning of the cell cycle, it is essential for the sister chromatids to be tethered together until the chromosomes are ready to separate. This process is collectively termed

as cohesion and is maintained by the multi-protein cohesin complex along with numerous auxiliary factors (Skibbens, 2009).

Cohesin complexes are evolutionarily conserved from yeast to humans and are composed of five core subunits, SMC1A, SMC3, RAD21/MCD1/SCC1, SA1,2/STAG1,2/Irr1/Scs3 and PDS5 (Figure 1.1). SMC1A and SMC3 are elongated ATPase proteins that together form a ring, which is stabilized by RAD21/ MCD1/SCC1. RAD21 in turn recruits the remaining components (PDS5 and either SA1 or SA2) (Jeppssen 2014; Marston 2014; Skibbens 2016). The exact mechanism through which DNA becomes entrapped within this flattened cohesin ring remains enigmatic, but could involve one, or more than one, cohesin rings. Cohesins are incapable of binding DNA spontaneously. Instead, a series of auxiliary factors are required for cohesins to bind DNA prior to functioning in chromosome segregation, chromatin condensation, DNA repair, and transcriptional regulation. The NIPBL/SCC2 and MAU-2/SCC4 deposition heterocomplex is required to load cohesins onto DNA segments (Ciosk 2000; Seitan 2006; Rollins 1999; Rollins 2004). The rules governing cohesin deposition are poorly understood. Once chromatin-bound, however, cohesins must become activated (promoting cohesin oligomerization and/or stabilizing DNA entrapment). The N-acetyltransferase family of proteins, ESCO2/EFO2/ESCO1/EFO1/Ctf7/Eco1 supplies this role. The ESCO families of protein are highly conserved acetyltransferases that activates SMC3 through acetylation, which is required for all subsequent cohesin-dependent activities (Skibbens et al., 1999; Toth et al., 1999; Ivanov et al., 2002; Bellows et al., 2003; Hou and Zou, 2005; Rolef Ben-Shahar et al., 2008; Zhang et al., 2008). Cohesins must also be turned off, either to allow for sister chromatid separation at anaphase onset

or to respond to transcriptional responses to external cues through tether disassembly/reassembly. Cohesin inactivation at anaphase onset is irreversible and occurs through RAD21 degradation, although a non-proteolytic release mechanism can reduce cohesin binding during prophase (Funabiki 1996; Ciosk 1998; Uhlmann and Nasmyth 1999; Shintomi and Hirano, 2010). On the other hand, cohesin inactivation during G1 likely occurs through disassociation of cohesin dimers. In both cases, HDAC8/Hos1 deacetylase helps reset the acetylation state of SMC3 (Xiong et al., 2010; Borges et al., 2010; Beckouet et al., 2010; Deardorff et al., 2012a).

## **1.2 Cohesion-mediated *trans* and *cis*-DNA tethering functions**

Historically, cohesins were identified for their role in the *trans*-DNA tethering mechanisms such as sister chromatid cohesion and segregation. But recently, numerous findings brought to light the *cis*-DNA tethering functions of cohesins (Figure 1.1). Cohesins function in stabilizing DNA loops by promoting or precluding registration of enhancers and promoters in close proximity. Other *cis*-DNA tethering roles of cohesins include condensation and ribosome biogenesis. Genome-wide studies report direct association of cohesin subunits and cohesin auxiliary factors with developmental genes. Thus one of the possible mechanisms that underlie the transcriptional regulation of cohesin is via long distance DNA looping. Additional studies from various groups show cohesin facilitates long distance DNA looping (Hadjur et al., 2009; Mishiro et al., 2009; Nativio et al., 2009; Hou et al., 2010). Interestingly, in mouse embryonic stem cells cohesin binding initiates enhancer-promoter interaction via DNA loops in transcriptionally active genes (Figure 1.2; Kagey et al., 2010). They provide *in vivo*

evidence of physical interaction and co-occupancy of the cohesin, mediator and NIBPL at the enhancer and core promoter regions of active genes. This group of researchers suggested that co-activator- bound mediator complex undergoes conformational changes and binds to the cohesin and NIBPL. This leads to the enhancer- promoter DNA loop formation and eventually overall gene activation. This study suggests the possibility that such long distance DNA looping may exist that affects the gene expression and thus results in various developmental disorders.

### **1.3 Cohesion pathway mutations leads to cohesinopathies**

Skeletal defects, especially long bone growth and morphogenesis, are components of a number of multi-spectrum developmental abnormalities. These include Roberts syndrome (RBS), Cornelia de Lange Syndrome (CdLS) (Krantz et al., 2004; Tonkin et al., 2004; Schule et al., 2005; Vega et al., 2005; Musio et al., 2006; Deardorff et al., 2007; Gordillo et al., 2008; Deardorff et al., 2012a; Deardorff et al., 2012b). Genetic mapping studies revealed that mutations in the genes of the cohesion pathway give rise to these diseases and thus grouped them into a common disease category collectively termed cohesinopathies.

RBS is characterized by pre- and postnatal growth retardation affecting the limbs and craniofacial bone structures. Dr. John B. Roberts reported the earliest case back in 1919 and thus named in his honor. All four limbs are affected in RBS patients such that children are born with shortened arm and leg bones. Facial abnormalities are significant symptoms of RBS, which includes cleft lip, cleft palate, small chin and corneal clouding (Berg and Francke, 1993; Vega et al., 2005). Infants born with severe forms of RBS are

stillborn and the mortality rate is quite high (Schule et al., 2005). To date, roughly 150 cases of RBS have been reported.

CdLS is a similar disorder that exhibits significantly overlapping and severe phenotypes as RBS. Both RBS and CdLS patients, in addition to severe long-bone growth defects and missing digits, exhibit craniofacial abnormalities, cleft palate, syndactyly, organ defects and severe mental retardation (Van den Berg and Francke, 1993; Schule et al., 2005; Vega et al., 2005; Liu and Krantz, 2009; Mannini et al., 2010). Figure 1.3 depicts the phenotypes observed in RBS and CdLS patients.

#### **1.4 Genetic basis of RBS and CdLS**

RBS is an autosomal recessive disorder that arises from mutations in the acetyltransferase *ESCO2* (Vega et al., 2005; Schule et al., 2005; Gordillo et al., 2008). In 2005, the gene responsible for RBS was identified and characterized as *ESCO2* (Establishment of Cohesion 1 homolog 2). The 30.3kb coding sequence is divided into 11 exons, with the start and stop codon on exon 2 and exon 11 respectively (Figure 1.4). *ESCO2* has a predicted size of 68.3 kDa and is evolutionarily conserved among vertebrate species (Vega et al., 2005). The C-terminal of *ESCO2* is similar to *Eco1/Ctf7* of yeast (Skibbens et al., 1999; Ivanov et al., 2002). *ESCO2* C-terminal is evolutionary conserved and belongs to the Eco1p family of proteins. These proteins have N-acetyltransferase activity and play an important role in the process of sister chromatid cohesion during the S phase of cell cycle. Table 1.1 lists the different names of the protein in various model organisms (Horsfield et al., 2012).

CdLS on the other hand is an autosomal dominant disorder that arises from heterozygous or X-linked mutations in the cohesion subunits *SMC1A*, *SMC3*, *RAD21*, as well as in the auxiliary factors *NIPBL* and *HDAC8* (Krantz et al., 2004; Tonkin et al., 2004; Musio et al., 2006; Deardorff et al., 2007; Deardorff et al., 2012a; Deardorff et al., 2012b). CdLS occurs approximately 1 in 10,000 live births (Opitz, 1985; Krantz et al., 2004), and around 65% of the reported cases arise from mutations in the *NIPBL* gene (Krantz et al., 2004; Tonkin et al., 2004; Zakari et al., 2015).

### **1.5 Mechanisms posited to produce RBS and CdLS**

Intriguingly, the mechanisms through which mutations contribute to cohesinopathies are thought to vary widely. Cells isolated from RBS patients exhibit chromosomal segregation defects, premature centromere separation (PCS), heterochromatin repulsion (HR), lagging chromosomes, aneuploidy, elevated levels of apoptosis and reduced cell proliferation which is consistent with the role of *Esco2* (Figure 1.5) (Schule et al., 2005; Vega et al., 2005; Gordillo et al., 2008; Mehta et al., 2013 and Horsfield et al., 2012). In contrast, cells from CdLS patients do not exhibit PCS/HR cellular morphology or mitotic defects (Krantz et al., 2004). Because of the distinct cellular phenotypes, defects in *trans*-DNA tethering events were initially believed to be the underlying cause of RBS. Whereas due to the lack of overt defects in *trans*-DNA tethering and early studies that linked *Drosophila Nipped B* (*NIPBL* homolog) to transcription regulation, the underlying cause of CdLS is largely modeled as occurring through defects in *cis* DNA-tethering (Figure 1.6). Analyses of various model systems reveal that multiple mechanisms within each syndrome may be at work (discussed in

review article, Banerji et al., 2017, in revision). Below, I discuss in detail the suggested mechanisms underlying both RBS and CdLS.

### **(1) Apoptosis is activated in both RBS and CdLS**

Currently the mechanism of RBS pathogenesis is unclear. To date, *ESCO2* mutations are the only etiologic genetic agent known to produce RBS. The popular model of RBS suggests reduced progenitor cell proliferation and increased mitotic failure accompanied by apoptosis as the underlying mechanism (Monnich et al., 2011). Studies using *ESCO2* knockout mice report both cohesion defects and roughly two-fold increase in apoptotic cells, similar to RBS patient cells (Whelan et al., 2012; Gordillo et al., 2008, van der Lelij et al., 2009 ). Similar findings are observed in studies using both zebrafish and medaka embryos, establishing teleosts as a powerful model from which to study the molecular pathologies that underlie RBS (Monnich et al., 2011; Morita et al., 2012). In zebrafish, *esco2* morpholinos (MO) cause lethality by 72 hours post fertilization (hpf), but reducing the dosage permits bone and cartilage development (Monnich et al., 2011). These *esco2* morphants exhibited craniofacial cartilage defects, under-developed jaws and shorter pectoral fins, characteristic of RBS phenotypes. They found RBS to arise through reduced progenitor cell proliferation and increased incidences of both mitotic failure and apoptosis.

Similar findings are observed in *esco2* mutants (Morita et al., 2012; Percival et al., 2015). By using Targeted Induced Local Lesions in Genomics (TILLING) approach one group found a missense mutation (R80S) that was responsible for the RBS-like phenotypes in the medaka (Morita et al., 2012). Interestingly, the phenotypes of the

homozygous *esco2*<sup>R80S</sup> mutants are very similar to the *esco2* morphants. *esco2*<sup>R80S</sup> mutants have a variety of clinical phenotypes arising from a single mutation. Recently, a study using zebrafish *esco2*<sup>hi2865</sup> mutant (with a retroviral insertion in intron 1 of a gene which has homology with *ESCO2* gene) reported the apoptotic response to be p53-dependent, consistent with mitotic failure. However, a subset of mutant cells exhibits normal mitoses, suggesting the potential for multiple mechanisms underlying RBS phenotypes (Percival et al., 2015).

Apoptosis may be an under-appreciated phenotype of CdLS, since there are reports that CdLS cells do not exhibit mitotic defects and apoptosis (Krantz et al., 2004). It is important to point out that there are reports however, of mitotic defects occurring in CdLS patient cell lines (Kaur et al., 2005). Moreover, there are reports of increased levels of apoptosis in zebrafish morphants for the cohesin subunits (*smc3*, *smc1a*, *rad21a*,) and the cohesin loading factor (*nipblb*) that give rise to CdLS in humans (Ghiselli, 2006; Fazio et al., 2016, Schuster et al., 2015; Pistocchi et al., 2013). Knockdown of cohesin subunits also exhibit p53-dependent apoptosis, consistent with cell death due to mitotic failure (Ghiselli, 2006; Schuster et al., 2015).

## **(2) Transcriptional deregulation underlie both RBS and CdLS**

There is strong evidence that suggests that CdLS arises from misregulation of developmental genes (Bose et al., 2012; Dorsett, 2010; Dorsett and Merckenschlager, 2013). It is now well established that cohesins regulate transcriptional processes involving transcription termination, enhancer-promoter registration, CTCF-insulator recruitment and RNAPII transition (Dorsett and Krantz, 2009; Cucco and Musio,

2016; Dorsett and Merckenschlager, 2013). But the extent to which cohesin and its auxiliary factors function through a single common mechanism or through multiple mechanisms remains an important developmental issue.

One mechanism includes long- distance DNA looping which plays an important part in cohesin-mediated gene regulation (Ball et al., 2014; Kagey et al., 2010). Cohesin recruitment to these loops involves the CCCTC-binding factor (CTCF) insulator. CTCF binds to specific DNA motifs and in turn recruits cohesins to these specific loci (Wendt and Peters, 2009; Hadjur et al., 2009; Hou et al., 2010; Kagey et al., 2010; Ball et al., 2014; Parelho et al., 2008; Rubio et al., 2008). In fact, studies from numerous model systems suggest that CTCF both precludes enhancer-promoter interactions through DNA looping and recruits cohesins for loop stabilization (Wendt and Peters, 2009; Degner et al., 2011; Nativio et al., 2011; Majumder and Boss, 2011; Guo et al., 2012). In mammalian cells, there is more than 50% overlap between cohesin and CTCF binding sites (Wendt et al., 2008). In zebrafish, cohesin both positively (i.e. CTCF independent) and negatively (i.e. CTCF-dependent) regulates transcription factor *runx1* expression (Rhodes et al., 2010). Intriguingly, Drosophila CTCF and cohesin colocalization appears reduced (Misulovin et al., 2008; Pauli et al., 2008; Van Bortle et al., 2014). In combination these findings suggest that while defects in CTCF recruitment of cohesin may contribute to cohesinopathies, additional mechanisms must be at play (Mourad and Cuvier, 2016).

In addition to CTCF, the transcription co-activator Mediator is implicated in cohesin-dependent transcription. Mediator is a large complex that recruits RNAPII to the promoter (Kagey et al., 2010; Conaway et al., 2005; Kornberg, 2005; Taatjes, 2010;

Malik and Roeder, 2005; Roeder, 1998). Mutations in the *Drosophila NIPBL* ortholog, *Nipped-B*, are linked to long-distance enhancer-mediated transcriptional changes that occur during development (Rollins et al., 1999; Dorsett, 2016). Evidence from embryonic stem cells suggests that Mediator participates in this cohesin-dependent DNA looping (Kagey et al., 2010), consistent with similar findings regarding transcription factor *hoxd* in zebrafish *nipbla/b* morphants (Muto et al., 2014). Changes in nuclear architecture in both *nipbla/b* and *med12* single morphants, suggesting that expression of these genes is indeed mediated through chromatin looping (Muto et al., 2014).

New studies provide a growing body of evidence that RBS models, similar to CdLS, exhibit significant changes in gene expression (Banerji et al., 2016; Choi et al., 2010; Leem et al., 2011; 288 Monnich et al., 2011; Xu et al., 2013; Xu et al., 2016; Rahman et al., 2015). Support for a transcriptional role of ESCO2 comes from studies using human cell lines that ESCO2 represses *Notch* transcription to promote neuronal differentiation (Leem et al., 2011). Interestingly, the study using *esco2*<sup>R80S</sup> medaka mutants show evidence of Esco2 functioning during embryogenesis by upregulating certain genes in the Notch pathway (Morita et al., 2012). Additionally, there is evidence that ESCO factors act as transcription repressors by recruiting chromatin modifiers (Choi et al., 2010; Kim et al., 2008). Additional evidence comes from the comparison of gene expression profiles from cohesin subunit, *rad21* null mutants (*rad21*<sup>nz171</sup>) and *esco2* morphants that show a number of overlapping genes with altered expression profiles (Rhodes et al., 2010; Monnich et al., 2011). Intriguingly, this common gene pool exhibited opposing directions in gene expression: genes upregulated in the *rad21*<sup>nz171</sup> mutant were downregulated in *esco2* morphant embryos, and vice versa. An explanation

for such opposing transcriptional effects is likely due to differences in the loss of structural components (cohesin) versus enzymatic activities (Esco2). For instance, cohesins may remain chromatin bound and/or CTCF associated in *esco2* morphants. Alternatively, opposing transcriptional effects between *rad21<sup>nz171</sup>* mutants and *esco2* morphants may reflect direct versus indirect roles in transcription.

Based on the findings from various model systems, it is certain that the etiologies of RBS and CdLS (or in general all cohesinopathies) are not straightforward, but rather quite complex. Reports of transcriptional deregulation and apoptosis in both syndromes suggest that multiple mechanisms are at play. This unifying model may appear to be challenged by disparate findings regarding NIPBL, cohesin and CTCF residency on chromatin (Misulovin et al., 2008; Kagey et al., 2010; Muto et al., 2011; Zuin et al., 2014; Minamino et al., 2015; Rahman et al., 2015). It is tempting to speculate that disparities in cohesin recruitment to DNA, as well as identified binding partners, reflect unique cohesin complexes that occur in different tissues and mediate different functions (i.e. transcriptional repression vs. activation). Further efforts in testing a unifying transcriptional basis for all cohesinopathies include identifying the mechanisms through which cohesins are deposited on specific loci, elucidating how chromatin-associated cohesins mediate *trans* versus *cis* conformations, and assessing how those complexes impact gene expression profiles.

## **1.6 Using the zebrafish caudal fin to distinguish between different RBS models**

The zebrafish regenerating fin is a powerful model system, which could provide valuable evidence to distinguish between different RBS models. For instance, the

zebrafish CNS, heart, gut, and cephalic structures appear exquisitely sensitive to cohesins and Nipbl levels (Muto et al., 2011; Pistocchi et al., 2013; Muto et al., 2014; Fazio et al 2016). Similar to humans, the zebrafish genome harbors orthologues of most cohesion genes (*nipbla* and *nipblb*, *esco1* and *esco2*, *smc1a* and *smc1al*, *smc3*, *rad21a* and *rad21b*, *stag1a/b* and *stag2a/b* and *stag3*; *pds5a* and *pds5b*). Gene function may be examined through generation of mutant alleles using genome editing (Hwang et al., 2013; Seruggia and Montoliu, 2014) or by the use of gene targeting MOs (Nasevicius and Ekker, 2000). Our lab uses the zebrafish caudal fin to study skeletal morphogenesis. Because of its simple structure, easy accessibility, rapid regeneration following amputation, limited cell type composition, and the ability to knock down gene expression through gene-specific MOs, this is emerging as an excellent model system to elucidate tissue and bone growth pathways (Iovine et al., 2005). Investigating how *Esco2* levels are affected in the zebrafish skeleton will provide new insights into the cohesinopathy field.

### **1.7 The fascinating process of zebrafish epimorphic fin regeneration**

The caudal fin is composed of 16 to 18 segmented bony fin rays or lepidotrichia with new growth occurring by the distal addition of bony segments and associated fin ray joints (Figure 1.7) (Haas, 1962; Goss et al., 1957). Each bony fin ray is made up of two concave hemirays that surrounds mesenchymal cells (Santamaria et al., 1992). These hemirays are lined by osteoblasts that secrete the bone matrix and primarily enclose the mesenchymal compartment, which consists of mesenchymal cells, blood vessels, nerves, melanocytes and fibroblasts. A layer of epithelial cells covers the entire fin and ontogenic

fin growth occurs by successive addition of bony segments to the distal tip of the fin (Haas, 1962).

Zebrafish are capable of impressive epimorphic regeneration in a variety of tissues such as caudal fin, skin, retina and heart. The process can be defined as a post-traumatic morphogenetic event where a specialized compartment of highly proliferating cells (blastema) are formed at the wound site by the aggregation of mesenchymal cells (Akimenko et al., 2003; Schebesta et al., 2006). Regeneration of the adult caudal fin is a fascinating process by which the lost tissue is restored in approximately 2 weeks following amputation (Figure 1.8). The 3 phases of the regeneration process consists of wound healing, blastema formation and regenerative outgrowth (Nechiporuk and Keating, 2002). The process of regeneration starts 12-24 hours post amputation (hpa) by wound healing by sealing the wound with migrating epithelial cells. After 12 hours there is thickening of the epidermis and the disorganized cells migrate towards the amputation plane to the blastema. It is important that a multilayered epidermis is formed during blastema formation and proliferation (Lee et al, 2009). The blastema consists of highly proliferative and undifferentiated cells that express different molecular markers such as *msxb* and *msxe* that label undifferentiated cells (Barker and Beck, 2009; Han et al., 2003). During the final regenerative outgrowth phase after 48-72 hpa, the blastema compartmentalizes into proximal and distal zones. After 72 hpa and later, outgrowth process takes place where cells migrate in both proximal and lateral directions (Nechiporuk and Keating, 2002).

## 1.8 CX43 is important for growth and development of vertebrate skeleton

Our lab uses the zebrafish regenerating fin as a tool to understand the molecular mechanisms regulating skeletal morphogenesis in vertebrates. Previously, our lab has established that homozygous mutations in a gap junction gene, *connexin43* (*cx43*) cause the short fin (*sof<sup>b123</sup>*) phenotype. The *sof<sup>b123</sup>* mutant is characterized by short bony fin ray segments, short fins, and reduced cell proliferation (Figure 1.9; Iovine et al., 2005 and Hoptak-Solga et al., 2008). Importantly, MO-mediated Cx43 knockdown in wild type regenerating fins also result in reduction in fin length, segment length and cell proliferation, recapitulating the phenotypes observed in *sof<sup>b123</sup>* mutants (Hoptak-Solga et al., 2008).

Gap junctions are intracellular channels that are formed by the docking of two connexons of neighboring cells and freely permit direct exchange of small ions, second messengers and low molecular weight metabolites (<1000Da) (Figure 1.10). The connexons or hemichannels are made up of six four-pass transmembrane spanning proteins called connexins. Gap junctions play a vital role in developmental processes, tissue function, homeostasis maintenance, morphogenesis, cell differentiation, and growth control in multicellular organisms and during the process of skeletogenesis (Oyamada et al., 2005). In order to understand the role of Cx43 during skeletal development I utilize a zebrafish short fin mutant (*sof<sup>b123</sup>*).

Cx43 exhibits conserved functions in the vertebrate skeleton. Mutations in *CX43* cause skeletal defects in human, mouse, chick and zebrafish. For example, pleiotropic developmental disorder, Occulodentodigital dysplasia (ODDD, Paznekas et al, 2003, Figure 1.11) is associated with missense mutations in human *CX43* gene. ODDD patients

exhibit skeletal and craniofacial abnormalities along with additional pleiotropic phenotypes such as eye and dental deformities. Also, a dominant mouse mutation in *CX43* exhibits various skeletal and pleiotropic phenotypes similar to human ODDD (Flenniken et al., 2005). Additional studies show that targeted gene knockdown of *CX43* in adult chicks and in chick embryos results in facial abnormalities (Makarenkova and Patel, 1999) and limb malformation (McGonnell et al., 2001). Thus, the regenerating fin provides clinically relevant insights into highly conserved pathways critical for human skeletal development.

### **1.9 Hypothesis and Research objective**

RBS and CdLS are pleiotropic developmental disorders exhibiting severe growth retardation resulting in limbs and craniofacial abnormalities. They are collectively termed cohesinopathies since both disorders comprise overlapping phenotypes and the causative genes for both syndromes perform common activities. It is therefore surprising that CdLS and RBS are considered separate syndromes. A consensus regarding underlying molecular mechanisms obtained from various model systems remains elusive. Due to distinct cellular morphology exhibited by RBS and CdLS patient cells, at present the molecular mechanisms through which cells and developing organisms respond to cohesion still remain unclear (Mehta et al., 2013; Horsfield et al., 2012; Dorsett and Merckenschlager, 2013). But certainly, the etiology of these disorders is much more complex, and does not fall into the categories typically defined by the different syndrome names. Analyses of various model systems reveal that multiple mechanisms within each syndrome may be at work. It is now well established that cohesins play a direct role in

gene expression and the developmental defects in CdLS patients arise due to transcriptional deregulation. But the role of apoptosis in CdLS cannot be completely ruled out. For instance, there are reports of cohesion defects and elevated levels of apoptosis in CdLS patient cells and zebrafish morphants (Kaur et al., 2005; Ghiselli et al., 2006; Fazio et al., 2016; Schuster et al., 2015). Currently, the role of apoptosis in CdLS is either underappreciated or not tested. On the other hand, mitotic failure and elevated levels of apoptosis is currently the popular model underlying RBS. Similar to cohesins, role of Esco2 has been reported in various *cis*-DNA tethering processes such as ribosome maturation and assembly, DNA repair and transcriptional regulation (Skibbens et al., 1999; Skibbens et al., 2010; Gard et al., 2009; Bose et al., 2012; Terret et al., 2009; Unal et al., 2004; Zakari et al., 2015; Leem et al., 2011). The growing bodies of evidence suggest a transcriptional mechanism underlying RBS, similar to CdLS. Considering the complexity in the mechanisms underlying these disorders, it is important to investigate the role of apoptosis and transcriptional deregulation underlying both diseases.

My research objective is to understand if CdLS and RBS occur as a result from a similar mechanism. Particularly I am interested to test the transcriptional mechanism underlying RBS using the zebrafish regenerating fin. Prior work on the regenerating fin revealed that *Cx43* is required for both cell proliferation and joint formation during fin regeneration (Iovine et al., 2005). Since human *CX43* mutations cause a pleiotropic skeletal disorder Oculodentodigital dysplasia (ODDD) that overlap with those of both RBS and CdLS (Paznekas et al., 2003), I posit that ODDD is linked to cohesinopathies and that transcriptional deregulation of developmental genes such as *CX43* may contribute to RBS phenotypes. My findings (discussed in the next chapters) suggest that

Esco2 and the cohesin subunit Smc3 function together to regulate *cx43* expression during skeletal development. My work sheds light on a unified underlying mechanism of RBS and CdLS and in general all cohesinopathies.

## 1.10 Figures and Tables

**Figure 1.1: DNA tethering mechanisms of cohesins and auxiliary factors.**

Schematic representation of the cohesin ring structure (composed of the 5 subunits; SMC1A, SMC3, RAD21, SA1,2 and PDS5) and auxiliary factors, NIPBL (loader), ESCO2 (acetyltransferase) and HDAC8 (deacetylase). Cohesins and auxiliary factors regulate both *cis* and *trans*-DNA tethering events. *Cis*-DNA tethering processes include DNA looping mechanisms during transcription, condensation and ribosome biogenesis. *Trans*-DNA tethering processes include sister chromatid segregation during S phase of cell cycle and DNA repair events

**Figure 1.3: Multifaceted developmental disorders: RBS and CdLS.** Characteristic features of RBS patients shown in left panel. Patients are characterized by skeletal deformities in limbs, missing digits, small head, cleft lip and palate. RBS limb reduction is mesomelic and symmetric in which the arms are more severely affected than the legs. Characteristic features of CdLS patients are shown in right panel. Patients are characterized by craniofacial abnormalities, organ defects and limb deformities. Variability of upper limb abnormalities and with missing and fused digits are commonly seen in CdLS patients.

Source: Photographs of RBS patients (left, Vega et al., 2005) and CdLS patients (right, Krantz et al., 2004)

**Figure 1.4: *ESCO2* gene structure with location of identified mutations.** Eight mutations identified in 15 families with RBS reported by Vega et al., 2005 (shown at the top). Seven mutations found in 5 families with RBS reported by Schule et al., 2005 (shown at the bottom). White boxes -UTR, gray boxes - coding regions of exons 2–11. Location of the functional domains—the C2H2 zinc finger-like domain (diagonal stripes) and the acetyltransferase domain (horizontal stripes) are shown.

**Figure 1.5: Cellular morphology of RBS patient cells.** The RBS patient cells exhibit characteristic railroad-track morphology (indicated with arrows), which is indicative of premature centromere separation (PCS) and heterochromatin repulsion. The arrowhead indicates the Y chromosome splitting in the heterochromatin region. Normal chromosomes are shown with open arrows.

Source: Vega et al., 2005

**Figure 1.6: Suggested models of cohesinopathies.** Currently the suggested models of CdLS and RBS are distinct. CdLS arises due to *cis*-DNA tethering defects resulting in transcriptional deregulation. In contrast, RBS arises due to defects in *trans*-DNA tethering resulting in mitotic defects and elevated levels of apoptosis.

**Figure 1.7: The zebrafish regenerating caudal fin is a model system for skeletal morphogenesis.** (Top) A caudal fin is stained with calcein that detects bone matrix, revealing 16-17 bony fin rays comprised of bony segments separated by joints. (Bottom left) Representative image of a transverse section through a single fin ray is shown. White arrows indicate hemirays that are visible as crescents of bone surrounding mesenchymal tissue (m). The bony rays are surrounded by the epithelium (e) and basal layer of epithelium is the region with purple stain. (Bottom right) Schematic of a longitudinal section of the fin showing the different compartments as follows: Blastema (b), mesenchyma (m), epidermis (e), skeletal precursor cells (spc) and lepidotrichia (lep). The amputation plane is indicated by a black dotted line.

**Figure 1.8: Stages of Fin regeneration.** The three stages of epimorphic regeneration consist of (1) wound healing, (2) blastema formation and (3) the regenerative outgrowth phase. During wound healing, epithelial cells migrate distally to cover the wound by forming an apical epithelial cap. The blastema is a specialized compartment of the regenerating fin, consisting of highly proliferative cells. Cells in the blastema are divided into two subsets: distal most blastema cells and cells that is highly proliferative. During the final regenerative outgrowth phase, the gradient of *msxb* expression and proliferation is maintained, controlling the direction of outgrowth. Cells in the proliferative zone (pz) move in the proximal direction to differentiate. A zone of negative proliferation in the distal most blastema (dmb) maintains the directionality of the outgrowth by inhibiting proliferation.

## CHAPTER 2

**Esco2 regulates *cx43* expression during skeletal regeneration in the zebrafish**

## 2.1 Abstract

Roberts syndrome (RBS) is a rare genetic disorder characterized by craniofacial abnormalities, limb malformation and often severe mental retardation. RBS arises from mutations in *ESCO2* that encodes an acetyltransferase and modifies the cohesin subunit SMC3. Mutations in *SCC2/NIPBL* (encodes a cohesin loader), *SMC3* or other cohesin genes (*SMC1*, *RAD21/MCD1*) give rise to a related developmental malady termed Cornelia de Lange Syndrome (CdLS). RBS and CdLS exhibit overlapping phenotypes, but RBS is thought to arise through mitotic failure and limited progenitor cell proliferation while CdLS arises through transcriptional deregulation. Here, I use the zebrafish regenerating fin model to test the mechanism through which RBS-type phenotypes arise. *esco2* is upregulated during fin regeneration and specifically within the blastema. *Esco2* knockdown adversely affects both tissue and bone growth in regenerating fins – consistent with a role in skeletal morphogenesis. *Esco2* knockdown significantly diminishes *cx43/gjal* expression, which encodes the gap junction connexin subunit required for cell-cell communication. *cx43/CX43* mutations cause the *short fin* (*sof<sup>b123</sup>*) phenotype in zebrafish and oculodentodigital dysplasia (ODDD) in humans. Importantly, *cx43* overexpression rescues *esco2*-dependent growth defects. These results conceptually link ODDD to cohesinopathies and provide evidence that *ESCO2* may play a transcriptional role critical for human development.

**This work is published as Banerji, R., Eble, D.M., Iovine, M.K. and Skibbens, R.V., 2016. *Esco2* regulates *cx43* expression during skeletal regeneration in the zebrafish fin. *Developmental Dynamics*, 245:7-21. Funding: Nemes Fellowship and Lehigh University Faculty Innovation Grant.**

## 2.2 Introduction

The skeleton supports soft tissues, provides for muscle attachment and protects internal organs from risk of injury. Additional functions include calcium and phosphorus storage, blood cell production and immune response. Given this diverse array of functionality, mutations that affect skeletal functions exhibit pleiotropic defects that include osteoporosis, osteoarthritis, hematopoietic and immunity deficiencies. Aberrations in skeletal development, especially long bone growth and morphogenesis, are also components of a number of multi-spectrum developmental abnormalities such as Roberts syndrome (RBS) and Cornelia de Lange Syndrome (CdLS). In addition to severe long-bone growth defects and missing digits, both RBS and CdLS patients may exhibit craniofacial abnormalities, cleft palate, syndactyly, organ defects and severe mental retardation (Liu & Krantz, 2009; Mannini et al, 2010).

Recent genetic mapping studies reveal that mutations in cohesion pathways are responsible for RBS and CdLS disorders – as well as a host of related diseases collectively termed cohesinopathies (Schule et al, 2005; Gordillo et al, 2008; Krantz et al, 2004; Musio et al, 2006; Tonkin et al, 2004; Vega et al, 2005; Deardorff et al, 2007; Deardorff et al, 2012a,b; Van der Leijj et al, 2010; Yuan et al, 2015). Elucidating the molecular basis of these disorders span topics of both chromosome segregation and transcriptional regulation (Rudra and Skibbens, 2013). For instance, RBS arises from mutations in *ESCO2*. High fidelity chromosome segregation requires that sister chromatids be identified from DNA synthesis (S-phase) to anaphase onset during mitosis (M-phase). Identity is achieved by cohesin complexes that tether together sister chromatids. *ESCO2* is an acetyltransferase that converts chromatin-bound cohesins to a

tether-competent state (Skibbens et al, 1999; Toth et al, 1999; Ivanov et al, 2002; Zhang et al, 2008; Unal et al, 2008; Ben-Shahar et al, 2008). Thus, it is not surprising that cells isolated from RBS patients exhibit mitotic failure, elevated levels of apoptosis, reduced proliferation and genotoxic hypersensitivities (Mehta et al, 2013; Horsfield et al, 2012). On the other hand, CdLS arises from mutations in the cohesin genes *SMC1A*, *SMC3* and *RAD21*, the cohesin deposition factor encoded by *NIPBL*, and the de-acetylase encoded by *HDAC8* that targets *SMC3* (Krantz et al, 2004; Musio et al, 2006; Tonkin et al, 2004; Deardorff et al., 2007; Deardorff et al, 2012a,b). Intriguingly, CdLS patient cells typically exhibit normal mitosis and retain a euploid genomic state, revealing that CdLS instead arises mainly through transcriptional deregulation (Liu & Krantz, 2009; Dorsett & Merkenschlager, 2013). A transcriptional basis of CdLS is supported by findings that cohesins are critical for 1) transcription termination, 2) enhancer-promoter registration, 3) CTCF-insulator recruitment and 4) RNAPII transitioning from a paused to elongating state (Dorsett & Merkenschlager, 2013). Despite the phenotypic similarities between RBS and CdLS, the role for ESCO2 in transcription remains undefined.

The zebrafish caudal fin contains 16 to 17 segmented bony fin rays with new growth occurring by the distal addition of bony segments and associated fin ray joints (Goss & Stagg, 1957; Haas, 1962). Because of its simple structure, rapid regeneration following amputation, and the ability to knockdown gene expression through gene-specific morpholinos, the zebrafish fin is emerging as an excellent model system from which to elucidate tissue and bone growth pathways. For instance, mutations in *connexin43* (*cx43*) cause the *short fin* (*sof*<sup>b123</sup>) phenotype, which is characterized by defects in bony fin ray growth and joint formation (Iovine et al, 2005; Hoptak-Solga et

al, 2008). Missense mutations in human *CX43* cause Oculodentodigital dysplasia (ODDD) - a genetic disorder that effects both craniofacial and distal skeleton limb development (Paznekas et al, 2003). Thus, the regenerating fin provides clinically relevant insights into highly conserved pathways critical for human skeletal development.

Esco2 knockdown studies in zebrafish and medaka embryos produce severe developmental defects – in part recapitulating RBS phenotypes (Monnich et al, 2011; Morita et al, 2012). Large-scale cell death and subsequent indirect or downstream effects, however, complicate interpreting the effects of Esco2 knockdown in these studies. Here, I report on the role of *esco2* during fin regeneration, in the absence of embryonic complications. The regenerating fin is an ideal system to study the effects of reduced *esco2* on the skeleton in that it avoids the possible confounding effects of reduced *esco2* during development previously reported (Monnich et al., 2011; Whelan et al., 2012). In this chapter, I provide details of results that reveal that *esco2* expression is upregulated in regenerating fins, particularly in the blastema, which is a specialized compartment that contains the majority of proliferative cells. Moreover, Esco2 knockdown results in defects in both fin regeneration and bony segment length. Importantly, the results reveal that Esco2 knockdown reduces *cx43* expression and diminishes Cx43 signaling pathways but does not globally reduce other gene expression pathways. In combination, these results suggest the possibility that Esco2 may act as a specific transcriptional regulator with targets that include *cx43*.

## **2.3 Materials and methods**

### **Statement on the ethical treatment of animals**

This work was carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. Lehigh's Institutional Animal Care and Use Committee (IACUC) (Protocol identification # 128, approved 11/16/2014) approved the protocols used for this manuscript. Lehigh University's Animal Welfare Assurance Number is A-3877-01. All experiments were performed to minimize pain and discomfort.

### **Housing and husbandry**

Zebrafish (*Danio rerio*) are housed in a re-circulating system built by Aquatic Habitats (now Pentair). Both 3L tanks (up to 12 fish/tank) and 10L tanks (up to 30 fish/tank) are used. The fish room has a 14:10 light:dark cycle. Room temperature (RT) is tightly regulated and varies from 27-29°C (Westerfield, 1993). Water quality is monitored automatically and dosed to maintain conductivity (400-600 µs) and pH (6.95-7.30). Nitrogen levels are maintained by a biofilter. A 10% water change occurs daily. Recirculating water is filtered sequentially through pad filters, bag filters, and a carbon canister before circulating over UV lights for sterilization. Fish are fed three times daily, once with brine shrimp (hatched from INVE artemia cysts) and twice with flake food (Aquatox AX5) supplemented with 7.5 % micropellets (Hikari), 7.5 % Golden Pearl (300-500 micron, Brine Shrimp direct), and 5 % Cyclo-Peeze (Argent).

## **Zebrafish strains and surgical procedures**

The zebrafish strains used were wild-type (C32), *sof*<sup>b123</sup> (Iovine & Johnson, 2000), and *Tg(hsp70:miR-133sp<sup>pd48</sup>)* (Yin et al, 2012). Caudal fin amputations, fin regeneration and harvesting were done as previously described (Sims et al, 2009; Ton & Iovine, 2013; Govindan & Iovine, 2014). Briefly, fish were first anaesthetized in 0.1% tricaine solution and their caudal fin rays amputated to the 50% level using a sterile razor blade and visualized using a dissecting scope. Fin regeneration proceeded until the desired time period depending on the type of experiment. At the required time point, the regenerated fins were harvested and fixed in 4% paraformaldehyde (PFA) in PBS overnight at 4°C. The fins were then dehydrated in 100% methanol and stored at 20°C until further use.

## **Gene knockdown by morpholino injection and electroporation**

All morpholinos (MOs) used were fluorescein-tagged and purchased from Gene Tools, LLC. The MOs were reconstituted in sterile water to a final concentration of 1mM. The sequences for MOs used are as follows: MO targeted against *esco2* (*esco2*-MO: 5'-CTCTTTCGGGATAACATCTTCAATC-3', from Monnich et al., 2011), *esco2* - 5-base mismatch control MO (*esco2*-MM: 5'-CTCTTTCCGCATAAGATGTTGAATC-3'), and Gene Tools standard control MO (5'-CCTCTTACCTCAGTTACAATTTATA-3'). Microinjection and electroporation procedures were carried out as described previously (Thummel et al, 2006; Hoptak-Solga et al, 2008; Sims et al, 2009). Briefly, caudal fins were amputated at 50% level. At 3 days post amputation (3 dpa), fish were anaesthetized and MOs injected using a Narishige IM 300 Microinjector. Approximately 50 nl of MO

was injected per ray into either the dorsal or ventral side of the regenerating fin tissue (approximately first 5 - 6 bony fin rays), keeping the other side uninjected. The uninjected side served as the internal control. Immediately after injection, both sides of the fin were electroporated using a CUY21 Square Wave electroporator (Protech International Inc). To minimize non-specific effects of the electroporation procedure, both sides of the fin were electroporated. The following parameters were used during electroporation: ten 50-ms pulses of 15 V with a 1 s pause between pulses. These fish were returned back to the system water for regeneration to proceed. After 24 hours (i.e. 1 day post electroporation (1 dpe), which is equivalent to 4 dpa, the injected side of the fins were evaluated by fluorescence using a Nikon Eclipse 80i Microscope (Diagnostic Instruments) to confirm MO uptake. The MO injected fins were evaluated for regenerate length, segment length, cell proliferation, cell death, *in situ* hybridization, and protein levels by western blots and RNA levels by qRT-PCR. For fins used for lysate preparation or for qRT-PCR, all fins were injected and electroporated prior to harvesting.

### **Regenerate length and segment length measurement and analysis**

At 4 dpe/7 dpa, MO injected (*esco2*-MO or *esco2*-MM) fins were calcein stained prior to measuring regenerate length and segment length (Du et al, 2001; Sims et al, 2009). Briefly, fish were allowed to swim for 10 minutes in 0.2% calcein (pH 7) at room temperature followed by swimming in fresh system water for another 10 minutes. The fish were anaesthetized and imaged using Nikon Eclipse 80i Microscope equipped with a SPOT-RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments). All measurements were performed on the longest fin ray (3<sup>rd</sup> fin ray) from

the ventral or dorsal most lobe of the caudal fin, as previously established (Iovine & Johnson, 2000). Images used to measure regenerate length and bone segment length were analyzed using Image Pro software. For fin regenerate length, measurements were based on amputation site to the distal tip of the 3<sup>rd</sup> fin ray. For bone segment length, the distance between the first two joints formed following regeneration was measured. For each experiment at least 6-8 fish were used per trial and at least 3 independent trials were performed. Student's t-test ( $P < 0.05$ ) was used for statistical analysis.

### **RNA probe preparation and in situ hybridization on whole mount and cryosectioned fins**

RNA probes were made using linear PCR product as template, where the T7 RNA polymerase-binding site was included in the reverse primer. The *cx43* template was made as described (Iovine et al, 2005). The *esco2* product was generated using gene-specific primers (forward primer- 5'AGCAGGGACCTTCTACAGCA3' and reverse primer 5'TAATACGACTCACTATAGGGGGGATCATCTGGAAGAACG3'). RNA probes were labeled with digoxigenin (DIG) following manufacturer instructions (Roche). *In situ* hybridization (ISH) was performed on wild-type (WT) fins of different time points (1, 3, 5 and 8 dpa) and 5 dpa *sof*<sup>*b123*</sup> fins. Briefly, fins were amputated at 50% level and harvested at the appropriate time point. For ISH on knockdown fins, MO (*esco2*-MO or *esco2*-MM) was injected and electroporated on WT-3 dpa fins and harvested after 24 hours (1 dpe/4 dpa). For ISH on whole mount fins the standard protocol was followed (Ton & Iovine, 2013; Govindan & Iovine, 2014). Note that for ISH on *transgenic hsp70:miR-133sp*<sup>*pd48*</sup>- positive and negative fins, at 3 dpa fish were heat shocked at 37°C

for 1 hour and harvested after 24 hours (1 dpe/4 dpa). For all ISH experiments, approximately 6-8 fins were used per trial and 3 independent trials were performed. A Nikon Eclipse 80i Microscope equipped with a SPOT-RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments) was used to acquire images.

ISH on sections was done as described with the following modifications (Smith et al, 2008). WT-5 dpa fins were first rehydrated sequentially by methanol-PBS washes, cryosectioned and stored at -20°C. Slides were defrosted for approximately 1 hour prior to hybridization and section locations marked with a hydrophobic barrier pen (ImmEdge Pen; PAP pen, VWR Laboratories). RNA probe was mixed with hybridization buffer: 1X salt solution (NaCl, Tris HCl, Tris Base, Na<sub>2</sub>HPO<sub>4</sub>, and 0.5 M EDTA), 50% deionized formamide (Sigma), 10% dextran sulfate, 1 mg/ml tRNA, and 1X Denhart's (Fisher) and denatured by incubating at 70°C for 5 minutes. The denatured probe mix was added to the sections and hybridized overnight at 65°C. Slides were washed at 65°C with a 1X SSC, 50% formamide and 0.1% Tween-20 solution, rinsed with MABT (100mM Maleic acid, 150mM NaCl, and 0.1% Tween-20) and incubated in a blocking solution (MABT, goat serum and 10% milk) for 2 hours. Anti- DIG antibody (1:5000) was diluted in MABT and the slides were incubated overnight at 4°C. Slides were washed 4X in MABT, 2X in Alkaline Phosphatase staining buffer (100mM Tris, pH 9.5, 50mM MgCl<sub>2</sub>, 100mM NaCl, and 0.1% Tween-20), then incubated overnight at 37°C in 10% polyvinyl alcohol staining solution and NBT/BCIP stock solution (Roche). The reaction was stopped by washing extensively with PBST. Sections were mounted in 100% glycerol and images acquired using a Nikon Eclipse 80i Microscope equipped with a SPOT-

RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments).

### **Immunoblotting and Esco2 antibody**

*Escherichia coli* lysates from cells expressing either GST or GST-Esco2 fusion protein (protein expression was induced using 0.3mM IPTG for 4 hours) were prepared as described (Gerhart et al, 2012). Briefly, cells from 1 ml of culture were pelleted and lysed using 50µg/ml lysozyme in lysis buffer (100mM Tris- HCl pH 7.5, 50 mM NaCl, 10mM EDTA pH 8, complete protease inhibitor cocktail, Roche). To this mixture, 2.2 N NaOH and 8% BME were added. Protein precipitation was carried out using 55% TCA followed by wash with 0.5% TCA. The protein pellets were resuspended in 2X SDS buffer. GST or GST-Esco2 were detected by western blot using anti-GST antibody (Santa Cruz, 1:5000) or affinity-purified anti-Esco2 (1:1000). Affinity purified polyclonal Anti-Esco2 was generated in rabbit against the N-terminal peptide LSRKRKHGSPDAESC (Genscript) and used at a concentration of 1:1000 for the non-competed western blot. For anti-Esco2 antibody specificity assay, identical gels were loaded with decreasing volumes of the GST-Esco2 protein samples. For the competed blot, the anti-Esco2 antibody was pre-incubated with the Esco2 peptide (100µM). The blots were incubated with primary antibody overnight at 4°C.

Fin lysates were prepared as previously described (Hoptak-Solga et al, 2008; Gerhart et al, 2012; Govindan & Iovine, 2014). Briefly, approximately 9-10 MO-injected (*esco2* MO or *esco2* MM) 1 dpe/4 dpa regenerating fins were pooled, and then suspended in incubation buffer (136.8 mM NaCl, 5.36 mM KCl, 0.34 mM Na<sub>2</sub>HPO<sub>4</sub>, 0.35 mM

KH<sub>2</sub>PO<sub>4</sub>, 0.8 mM MgSO<sub>4</sub>, 2.7 mM CaCl<sub>2</sub>, 20 mM HEPES with pH adjusted to 7.5) supplemented with protease inhibitor (Thermo scientific, Halt<sup>TM</sup> Protease and Phosphatase Inhibitor Cocktail, 100X). The harvested fin tissue was homogenized by a tissue homogenizer (Bio-Gen, PRO 200) at high speed (3X) for 5 seconds with 10 second cooling intervals. Homogenized samples were centrifuged at 200g for 10 min at 4°C and supernatant protein levels normalized according to Bradford assays. Note that for preparation of proteins lysate from heat shocked *Tg(hsp70:miR-133sp<sup>pd48</sup>)* – positive and *Tg(hsp70:miR-133sp<sup>pd48</sup>)* –negative fish, 37°C heat shock was performed for 1 hour at 3 dpa and fins harvested at 1 dpe/4dpa as previously described.

GST, Esco2, Cx43 or tubulin was detected using anti-GST (1:5000) (Santa Cruz), anti- Esco2 (1:1000), anti-Cx43 (1:1000) or anti- $\alpha$ -tubulin (1:1000) (Sigma), followed by exposure to peroxidase-conjugated goat anti-rabbit IgG (GST, Esco2 and Cx43) or goat anti-mouse IgG (tubulin) (Pierce Rockford, IL) at a concentration of 1:20,000. Signal detection was performed using ECL chemiluminescent reagent (SuperSignal West Femto Maximum Sensitivity Substrate, Pierce Rockford, IL) and X-ray film.

Image J software was used to calculate the band intensities and the percent change was calculated. Relative pixel densities of gel bands were measured using a gel analysis tool in ImageJ software as described (Bhadra and Iovine, 2015). The density of each band was obtained as the area under the curve using the gel analysis tool. For relative density calculation, the density of the Esco2, Cx43 or tubulin bands for the experimental sample was first normalized against the density of the Esco2, Cx43 or tubulin bands from the control sample. Relative pixel density was calculated as the ratio of Esco2 and tubulin or Cx43 and tubulin, where tubulin is the loading control.

### **Cell proliferation and cell death assays**

For detection of proliferating cells in S-phase, bromodeoxyuridine (5-bromo-2'-deoxyuridine, BrdU) labeling was performed with few modifications (Nechiporuk & Keating, 2002, Iovine et al, 2005). Briefly, 3 dpa MO injected (*esco2*-MO or *esco2*-MM) fish were allowed to swim for 5 minutes in 50µg/ml of BrdU (Roche) mixed in system water at 1 dpe/4 dpa and harvested on the same day. The BrdU-labeled fins were fixed in 4% PFA overnight at 4°C and then dehydrated by keeping in 100% methanol overnight. Before use, the fins were rehydrated gradually in a series of methanol solutions containing 0.1% Triton X-100 in PBS (PBTx). Next, fins were treated for 30 minutes in a solution containing 2N HCl in PBTx. Following that, the fins were blocked for 2 hours (0.25% BSA in PBTx). The primary antibody against BrdU (Roche) is a mouse monoclonal and used at a 1:50 dilution and incubated overnight at 4°C. Extensive washes (4 hours) in the PBTx solution were performed the next day and fins incubated overnight at 4°C in 1:200 dilution of anti-mouse antibody conjugated to Alexa-546 (Invitrogen). The next day extensive washes (4 hours) were performed and the fins mounted in 100% glycerol and visualized under a Nikon Eclipse 80i Microscope equipped with a SPOT-RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments). For measuring BrdU labeled cells the Image Pro software was used. A ratio of distance migrated by BrdU positive cells from the regenerating tip in µm (a) and the regenerating length in µm (b) was calculated. BrdU labeling was then obtained by measuring a/b ratio of the uninjected and injected (*esco2*-MO and *esco2*-MM) side of the fin.

For both histone-3-phosphate (H3P) and Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assays, 3 dpa MO-injected (*esco2*-MO or *esco2*-MM) fins were harvested at 1 dpe/4 dpa and fixed in 4% PFA overnight at 4°C. These fins were then dehydrated in 100% methanol overnight before use. In order to detect mitotic cells, H3P staining and the number of H3P positive cells per unit area were carried out as described previously (Ton & Iovine, 2013). The primary and secondary antibodies used for H3P assay are as follows: rabbit anti-histone-3-phosphate (1:200) (anti-H3P, Millipore) and anti-rabbit Alexa 546 (1:200) (Invitrogen). H3P- positive cells were counted without software from within the distal-most 250µm of the 3<sup>rd</sup> fin ray as previously established (Iovine et al, 2005; Hoptak-Solga et al, 2008).

TUNEL assay (ApopTag Kit, Chemicon) was performed as described in the manufacturer's instructions with the following modifications. The fins were rehydrated by successive washes in methanol/PBST, treated with proteinase K at a concentration of 5µg/ml for 45 minutes at room temperature, and then re-fixed in 4% PFA in PBS for 20 minutes. After extensive PBST washes, fins were incubated in ethanol: acetic acid (2:1, v: v) at -20°C for 10 minutes. Following extensive PBST washes, fins were incubated in equilibrium buffer (from ApopTag Kit) for 1 hour at room temperature, and then incubated overnight in 37°C water bath in TdT solution. The enzymatic reaction was stopped by extensive washes in stop/wash buffer for 3 hours in 37°C water bath, briefly rinsed in PBST and blocked with blocking solution (from ApopTag Kit) for 1 hour. The fins were incubated overnight at 37° in Rhodamine antibody solution (from ApopTag Kit). Fins were washed extensively in PBST and then mounted in 100% glycerol. Image acquisition was performed using a Nikon Eclipse 80i microscope equipped with a SPOT-

RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments). Cell death was analyzed by counting the number of TUNEL-positive cells without software from the distal-most 250  $\mu\text{m}$  of the 3rd fin ray, similar to the H3P-positive cell counting analysis. For all the experiments at least 6-8 fins were used per trial and at least 3 independent trials were performed. Student's t-test ( $P < 0.05$ ) was used for statistical analysis.

### **Quantitative real- time PCR analysis**

Quantitative real- time PCR analysis (qRT-PCR) was completed on total mRNA extracted from 1 dpe/4 dpa harvested fins (3 dpa *esco2*-MO and standard control-MO injected). Total RNA extraction was carried out by following the standard protocol (Sims et al, 2009). Briefly, Trizol reagent (Gibco) was used to extract mRNA from minimum of 10 fins. For making cDNA, 1 $\mu\text{g}$  of total RNA was reverse transcribed with SuperScript III reverse transcriptase (Invitrogen) using oligo (dT) primers. The following primers (2.5 $\mu\text{M}$ ) for *keratin*, *cx43* (Sims et al, 2009), *sema3d* (Ton & Iovine, 2013), *hapln1a* (Govindan & Iovine, 2014), and *mps1* (Bhadra & Iovine, 2015) were used for qRT-PCR analysis. The primers for *shh* and *spry4* were designed using Primer express software (*shh*: forward primer: 5'-GGCTCATGACACAGAGATGCA-3', reverse primer: 5'-CATTACAGAGATGGCCAGCGA-3' and *spry4*: forward primer: 5'-CGCAACGACCTGTTCATCTGA-3', reverse primer: 5'-GCACTCTTGCATTTCGAAAGCA-3'). Data from three independent *Esco2* knockdown RNA samples were used, with qRT-PCR for each gene performed in duplicate, for comparison between experimental treatments. RNA and subsequent cDNA synthesized

from standard control MO injected fins served as the control. The standard control MO does not target any zebrafish genes. Analyses of the samples were done using Rotor-Gene 6000 series software (Corbette Research) and the average cycle number ( $C_T$ ) determined for each amplicon. *Keratin* was used as a housekeeping gene, and the delta  $C_T$  ( $\Delta C_T$ ) values represent expression levels normalized to *keratin* values.  $\Delta\Delta C_T$  values represent the relative level of gene expression and the fold difference was determined using the  $\Delta\Delta C_T$  method ( $2^{-\Delta\Delta C_T}$ ) as described (Ton and Iovine, 2013). Standard deviation was calculated using the comparative method described in User Bulletin 2 # ABI PRISM 7700 Sequence Detection System ([http://www3.appliedbiosystems.com/cms/groups/mcb\\_support/documents/generaldocuments/cms\\_040980.pdf](http://www3.appliedbiosystems.com/cms/groups/mcb_support/documents/generaldocuments/cms_040980.pdf)).

### **Heat shock induction of *cx43* expression**

*Tg(hsp70:miR-133sp<sup>pd48</sup>)* are denoted as transgene-positive (Tg+) and their siblings denoted as transgene-negative (Tg-) were used in the heat shock experiment (Yin et al, 2012). For all the experiments at least 6-8 fish were used per trial and at least 3 independent trials were performed. *Esco2* knockdown was performed on 3dpa Tg+ and Tg- fish as described above. After 4 hours both groups were heat shocked at 37°C for 1 hour and returned to the system water for recovery. Tg+HS+ and Tg-HS+ denoted these groups respectively. To confirm that rescue depended on *cx43*, we also examined phenotypes in the transgenic line without heat shock (Tg+HS-). Induction of the transgene expression upon heat shock was confirmed after 24 hours by screening for GFP-positive fins in the Tg+HS+ group. The control groups (Tg-HS+ and Tg+HS-) were

negative for GFP expression after heat shock. For measurement of regenerate length and segment length fins were harvested at 4 dpe/7 dpa and calcein stained as previously described (Du et al, 2001; Sims et al, 2009). The measurement and data analysis were done as described below. Image acquisition was carried out by using the Nikon Eclipse 80i microscope equipped with a SPOT-RTKE digital camera (Diagnostic Instruments) and SPOT software (Diagnostic Instruments). Image Pro software was used for regenerate and segment length measurements.

To evaluate the regenerate length and segment length of *Tg(hsp70:miR-133sp<sup>pd48</sup>)* fins, the *esco2*-MO injected side of each fin was compared to its un-injected side by % similarity method as described (Bhadra and Iovine, 2015). Briefly, the length of the injected side and uninjected sides were measured in  $\mu\text{m}$  and denoted as A and B respectively. The % similarity for each fin was calculated by using the formula:  $[(A/B) \times 100]$ . Values close to 100% indicate that the *esco2*-MO has no effect on the phenotype whereas a value less than 100% indicate that the MO has an effect on the observed phenotype. The mean of % similarity for the *Esco2* knockdown experimental group (*Tg*+HS+) and the corresponding *Esco2* knockdown control groups (*Tg*-HS+ and *Tg*+HS-) were estimated and compared, and the statistical significance between the groups was determined using two-tailed unpaired student's *t*-test ( $P < 0.05$ ). Segment length analysis was performed on calcein stained fins. Briefly, for segment length, the distance between the first two newly formed joints following amputation was measured (in the 3<sup>rd</sup> fin ray from either the dorsal or ventral end) since that was previously established as a standard (Iovine & Johnson, 2000). To evaluate the phenotypic effect of segment length, the % similarity method was used as described above.

## 2.4 Results

### ***esco2* mRNA is upregulated in the blastema of regenerating fins**

Despite the fact that *ESCO2* is critical for proper human development (Schule et al, 2005; Vega et al, 2005), little information exists regarding its expression or the molecular basis through which mutations in *ESCO2* result in skeletal disorders. Here, I exploit the adult zebrafish regenerating fin to address both of these fundamental issues in the absence of confounding effects due to embryonic death. To ascertain the temporal regulation of *esco2* expression in regenerating fins, fins were amputated at the 50% level and regenerating tissue harvested at 1, 3, 5 and 8 days post amputation (dpa). The expression of *esco2* was then assessed by whole mount *in situ* hybridization (Figure 2.1). At 1 dpa, *esco2* was not detectable. *esco2* was readily apparent at both 3 and 5 dpa with levels starting to diminish at this later time point. By 8 dpa, *esco2* expression was significantly reduced. High *esco2* expression at 3 dpa is consistent with previous studies that map this period as the peak rate of regeneration in the zebrafish fin (Hoptak-Solga et al, 2008; Lee et al, 2005) and suggest that the localization of *esco2* expression might similarly correlate with the highly proliferative blastemal compartment. To test this possibility, 5 dpa fins stained for *esco2* expression by *in situ* hybridization were cryosectioned. The results reveal that *esco2* expression is specifically upregulated in the blastemal compartment (Figure 2.2). To establish that the probe had access to all *esco2*-positive tissue, 5 dpa fins were cryosectioned prior to hybridization (Smith et al, 2008). Results from this regimen confirm that *esco2* is expressed specifically within the blastema (Figure 2.2). In summary, *esco2* expression is temporally regulated and occurs specifically in the blastemal compartment of the zebrafish regenerating fin.

### ***esco2* is a critical regulator of fin regeneration and specifically of bone growth**

*Esco2* is likely essential (Monnich et al, 2011), requiring knockdown strategies to ascertain function in the adult regenerating fin. Therefore, I depleted *Esco2* using morpholino (MO)-mediated knockdown methodologies (Hoptak-Solga et al, 2008; Sims et al, 2009) using one of the two validated MOs for *Esco2* (Monnich et al, 2011). As a control I used either a custom mismatch morpholino (5MM) containing five mismatches compared with the *esco2* targeting MO or the ‘standard control’ MO from Gene Tools that does not recognize target genes in zebrafish. Uptake is accomplished by first injecting the MO into the blastema of the regenerating fin, followed by electroporation across the fin. All MOs are modified with fluorescein, permitting validation of cellular uptake. Only fins positive for MOs at 1 day post electroporation (dpe) are kept for further analysis. Procedural details for all knockdown experiments are outlined in Figure 2.3.

Regenerate length and segment length were evaluated at 4 dpe/7 dpa. All fin regenerate and segment length measurements were obtained from the 3<sup>rd</sup> fin ray and results compared between injected (*esco2*-MM or *esco2*-MO) and uninjected portions of the same fin, a strategy previously documented as providing for both internal controls and standardized analyses (Hoptak-Solga et al, 2008; Iovine & Johnson, 2000). Uninjected control fins regenerated in a robust fashion. *esco2*-MM injected regenerating fins exhibited identical growth to the uninjected control (Figure 2.4). In contrast, regenerating fins injected with the *esco2*-MO exhibited a significant decrease in regenerate length compared to uninjected controls within the same fins (Figures 2.4), documenting that *esco2* is critical for fin regeneration.

Roberts syndrome patients exhibit significant bone growth deficiencies - especially in the arms and legs (Mehta et al, 2013; Horsfield et al, 2012). Thus, it became important to quantify the extent that *esco2* depletion may specifically impact bone segment growth in regenerating fins. To address this question, segment length was measured in uninjected, *esco2*-MM and *esco2*-MO injected fins. The results show that segment length in uninjected fish was nearly identical to that of *esco2*-MM injected fish (Figure 2.4). However, segment length was significantly reduced in *esco2*-MO injected fish compared to the uninjected side of the same fish fins (Figure 2.4). Thus, *esco2* is critical for bone growth in regenerating fin, consistent with its role in skeletal development in humans.

To confirm that the *esco2*-MO was effective in reducing Esco2 protein levels, I generated an antibody against Esco2 and verified its specificity using bacterial lysates expressing GST-Esco2. The results show that anti-Esco2 antibody recognizes GST-Esco2, which migrates at the predicted size of 94 kDa. The anti-GST antibody also recognizes the GST-Esco2 band at the predicted size of 94 kDa and a 26 kDa band in the GST alone lane (Figure 2.5). The anti-Esco2 antibody does not recognize GST alone. To confirm the specificity of the anti-Esco2 antibody, a peptide competition assay was performed. Esco2-directed antibody was pre-incubated with the peptide that the antibody was generated against. The resulting competed antibody produced a greatly reduced signal, compared to non-competed antibody, when used to detect GST-Esco2, confirming antibody specificity (Figure 2.5). Upon validating the specificity of the Esco2-directed antibody, I tested the effectiveness of the *esco2*-MO to knockdown Esco2 levels in vivo. At 3 dpa, fins were injected with either *esco2*-MM or *esco2*-MO and harvested the next

day (1 dpe/4 dpa) to prepare fin lysate (see also Figure 2.3). The lysates were used to test for Esco2 reduction by western blot. Quantification of the resulting western blots shows that the *esco2*-MO reduces Esco2 protein levels by approximately 70% while robust levels of Esco2 persist in MM injected fins (Figure 2.5). The results of the Western blot analyses document the efficacy of the *esco2*-MO to significantly reduce Esco2 protein levels.

### **Role of *esco2* in cell proliferation and programmed cell death**

Reduced tissue and bone segment growth in regenerating fins could be due to decreased cell proliferation, increased programmed cell death (PCD), or both. In order to address possible changes in the level of cell proliferation, I evaluated both 5-bromo-2'-deoxyuridine (BrdU) as a marker for S-phase (Iovine et al, 2005) and histone-3-phosphate (H3P) as a marker for M phase (Wei et al, 1999). Morpholino-injected fish (where half of the fin was injected with either *esco2*-MO or *esco2*-MM, see also Figure 2.3) were allowed to swim in water supplemented with BrdU at 1 dpe/4 dpa and harvested on the same day. To quantify BrdU staining through which BrdU incorporation could be directly compared between the two fin halves, I compared the ratio of the BrdU-positive domains in the regenerating tip to the total regenerate length. As expected, *esco2*-MM injected and uninjected fins exhibited nearly identical ratios of BrdU labeled cells to regenerate fin length. In contrast, *esco2*-MO injected and uninjected sides produced a significant decrease in the ratio of BrdU labeled cells to regenerate length (Figure 2.6). Next I evaluated H3P-positive cells at 1 dpe/4 dpa (see also Figure 2.3). To compare H3P-positive cells between *esco2*-MM and MO injections in fin halves of the

same fin, I counted the total number of H3P-positive cells in the 250 mm area that defines the proliferative blastema, normalizing for the area (Nechiporuk et al, 2003). Regenerating fins in which one fin half was uninjected and the other half injected with *esco2*-MM exhibited nearly identical numbers of H3P-positive cells within this defined area (Figure 2.6). In contrast, the *esco2* MO-injected side exhibited a statistically significant reduced level of H3P-staining cells compared to the uninjected sides of the fins (Figure 2.6). Thus, cell proliferation appears to play a critical role in skeletal regrowth defects that occur in regenerating fins depleted of Esco2.

To address the possibility that PCD is increased in Esco2 depleted fins, fins were injected with either *esco2*-MM or *esco2*-MO on one half of the fin, the other half uninjected, and the fins were harvested 1 dpe/4 dpa for TUNEL staining (see also Figure 2.3). Importantly, I did not detect a noticeable difference in the number of TUNEL-positive cells between the *esco2*-MO injected side and the uninjected side of the same fins (Figure 2.7). Statistical analysis confirms that similar numbers of apoptotic cells are present in Esco2 knockdown and uninjected sides of the same fins (Figure 2.7). Thus, it appears, that regenerate and bone growth defects that occur upon Esco2 knockdown can be separated from increased levels of PCD.

### ***esco2* and *cx43* appear to function in a common pathway**

The pattern of *esco2* expression and localization during fin regeneration, coupled with impact of *esco2* depletion on bone segment regrowth, are strikingly similar to those previously reported for *cx43* mutations that cause the *short fin (sof<sup>b123</sup>)* phenotype (Iovine et al, 2005; Hoptak-Solga et al, 2008). Could Esco2 and Cx43 function in a common pathway to influence

bone segment growth? To address this possibility, I first tested whether *Esco2* function is downstream of *Cx43*. If true, then *esco2* expression might be reduced in *sof<sup>b123</sup>* mutant fins. Whole mount *in situ* hybridization was performed to monitor *esco2* message levels in wild type (WT) and *sof<sup>b123</sup>* regenerating fins. The results show that *esco2* expression levels are nearly identical in regenerating WT and *sof<sup>b123</sup>* fins (Figure 2.8), suggesting that *esco2* is not downstream of *cx43*. An alternate possibility is that *cx43* is downstream of *esco2*. Whole mount *in situ* hybridization was performed on *Esco2* knockdown fins (1 dpe/4 dpa, see also Figure 2.3) to determine if *cx43* expression is reduced in the half of the fin injected with *esco2*-MO (Figure 2.9). Indeed, *cx43* was reduced in fin rays injected with *esco2*-MO and not reduced in either MM control or uninjected controls (Figure 2.9). To independently test for *cx43* dependency on *esco2*, I performed qRT-PCR at 1 dpe/4 dpa (see also Figure 2.3). The results from 3 independent *Esco2* knockdown samples show that *cx43* is significantly down regulated in *Esco2* knockdown regenerating fins (Table 2.1; Figure 2.10). Since reduced cell proliferation is not sufficient to cause reduced *cx43* expression (Govindan & Iovine, 2014; Bhadra & Iovine, 2015), the observed reduction of *cx43* expression is not likely the result of reduced cell proliferation in *Esco2* knockdown fins. In combination, these findings support a model where *Cx43* acts downstream of, and may be regulated by, *Esco2*.

To further examine the possibility that *Esco2* and *Cx43* function in a common pathway, I next evaluated expression of both *semaphorin3d* (*sema3d*) and *hyaluronan and proteoglycan link protein 1a* (*hapln1a*), two genes recently found to function downstream of *cx43* (Ton & Iovine, 2013; Govindan & Iovine, 2014). If *esco2* is required for *cx43* expression, then *esco2* depletion should also repress these *cx43* targets. I examined the expression levels of *sema3d* and *hapln1a* using qRT-PCR on 3 dpa

regenerating fins injected with *esco2*-MO compared to the standard control morpholino. The results show that both *sema3d* and *hapln1a* are significantly down regulated in MO-injected regenerating fins (Table 2.1; Figure 2.10), consistent with the model that Esco2 regulates Cx43 signaling pathways that are critical for development. To exclude the possibility that Esco2 depletion represses all gene expression, I evaluated expression levels of three genes not known to be *cx43*-dependent, *sonic hedgehog* (*shh*), *sprouty 4* (*spry4*) and *mono polar spindle* (*mps1*) (Laforest et al, 1998; Lee et al, 2005; Poss et al, 2002). Expression levels of these genes are not reduced, demonstrating that Esco2 depletion does not lead to global gene repression. Both *shh* and *spry4* appear to be modestly upregulated, which could suggest either that Esco2 antagonizes these genes or that Esco2-dependent disruption of cell proliferation indirectly affects gene expression in these pathways. In combination, these results reveal that Esco2 acts as a transcriptional regulator with targets that include *cx43*.

If *cx43* truly acts downstream of Esco2 and *cx43* reduction in part mediate the bone growth defects observed upon Esco2 knockdown, then I reasoned that *cx43* overexpression might attenuate the regenerate and bone segment growth defects in regenerating fins. To test this prediction, I next attempted to rescue *esco2*-dependent skeletal growth defects by overexpression of *cx43*. I utilized the *Tg(hsp70:miR-133sp<sup>pd48</sup>)* line that harbors an EGFP cDNA followed by three miR-133 binding sites (Ebert et al, 2007; Loya et al, 2009). Prior studies found that miR-133 knockdown via this “sponge” transgene increases *cx43* levels during zebrafish heart regeneration (Yin et al, 2012). I confirmed upregulation of both *cx43* mRNA and Cx43 protein in regenerating fins of this transgenic line treated for heat shock (Figure 2.11). Moreover, to rule out the

possibility that increased Cx43 leads to an increase in Esco2, I further confirmed that the levels of *esco2* mRNA and Esco2 protein are not upregulated in this transgenic line treated for heat shock (Figure 2.11).

Either transgenic-positive (Tg+) or transgenic-negative (control siblings, Tg-) fins were treated for Esco2 knockdown (Figure 2.12). Four hours post electroporation, Tg+ and Tg- fish were both heat shocked (HS+) at 37°C for 1 hour. These fish are denoted as Tg+HS+ and Tg-HS+, respectively. Alternatively, a second group of Esco2 knockdown Tg+ fish was not heat shocked and thus denoted as Tg+HS-. To demonstrate that heat shock alone does not rescue *esco2*-dependent phenotypes, I performed Esco2 knockdown in Tg-HS+. Results from 3 independent trials show that Esco2 knockdown in Tg-HS+ exhibited the predicted growth defects for regenerate fin and bone segment lengths (i.e. the percent similarity between the Esco2 knockdown side and the uninjected side is low) (Figure 2.12). In contrast, Esco2 knockdown followed by induction of the transgene (causing *cx43* over-expression) in Tg+HS+, exhibited increased regenerate length and segment length, demonstrating Cx43-dependent rescue of the Esco2 knockdown phenotypes (i.e. the percent similarity between the Esco2 knockdown side and the uninjected side is significantly increased when *cx43* is overexpressed). I performed the same experiment using *esco2*-MM construct as a negative control. As expected, I did not observe skeletal phenotypes in these fins (data not shown). In order to demonstrate that the rescue of phenotype is heat shock dependent and therefore requires overexpression of *cx43*, I performed the same Esco2 knockdown experiment in the absence of heat shock in Tg+ fish (Tg+HS-). Importantly, I did not observe rescue of skeletal phenotypes in fish that carry the transgene but in which I do not induce its expression via the heat pulse

(Figure 2.12). The combination of these experiments provide compelling evidence that *Esco2* and *Cx43* function in a common pathway, and that the observed *esco2*-dependent skeletal phenotypes are at least partially mediated by reduced *cx43* expression.

## 2.5 Discussion

Cohesinopathies are a growing collection of severe and phenotypically pleiotropic developmental maladies, but at present the molecular mechanisms through which cells and developing organisms respond to cohesion mutations remains unclear (Mehta et al, 2013; Horsfield et al, 2012; Dorsett & Merkenschlager, 2013; Barbero, 2013). For instance, CdLS appears to arise through transcriptional deregulation that occurs in response to heterozygous or X-linked mutations in *NIPBL*, *SMC1*, *SMC3*, *RAD21*, *HDAC8* or *PDS5* (Krantz et al, 2004; Musio et al, 2006; Tonkin et al, 2004; Deardorff et al, 2007; Deardorff et al, 2012a,b; Gillis et al, 2004; Zhang et al, 2009). In contrast, the sister cohesinopathy RBS, which arises through homozygous mutation of *ESCO2* (Schule et al, 2005; Gordillo et al, 2008; Vega et al, 2005), is thought to arise instead through reduced progenitor cell proliferation and increased mitotic failure and apoptosis (Mehta et al, 2013; Horsfield et al, 2012; Whelan et al, 2012). My current studies suggest that *Esco2* is a critical and specific transcription regulator – leading us to speculate that RBS is most likely a transcriptional deregulation malady. Support for this model is three-fold. First, *Esco2* knockdown reduces transcription of specific cell signaling pathways such as *cx43*, mutations in which disrupt proper development (Paznekas et al, 2003; Musa et al, 2009; Iovine et al, 2005), but not other developmentally relevant signaling pathways such as *shh* (Table 2.1; Figure 2.10). Second, recent evidence reveals that *Esco2* regulates Notch signaling through binding/sequestration of the intracellular Notch domain (Leem et al, 2011). Notch is required for neuronal differentiation, skeletal development and hematopoietic lineages – consistent with pleiotropic phenotypes that result in both *esco2* and *notch* mutations (Zanotti & Canalis, 2013). Third, my results reveal no significant

increase in the incidence of apoptotic cells following *Esco2* knockdown in the blastemal compartment of regenerating fins. At present, I cannot exclude the possibility that a small increase in apoptotic cells is masked by a low but consistent background level required for remodeling in the regenerating fin, but the fact that elevated levels were not discernible in MO-injected fins compared to MM-injected and uninjected matched-fin controls suggests instead that the effects on fin and bone segment regeneration can occur independent of apoptosis. These findings contrast studies involving *Esco2* knockdown in zebrafish and medaka embryos and mice in which reproducible elevations in apoptotic cells were reported (Monnich et al, 2011; Morita et al, 2012; Whelan et al, 2012). However, the effects in those studies are modest. *ESCO2* knockdown in mice neuroepithelium, for instance, produced severe microcephaly but succeeded in inducing only a 2-fold increase in the number of apoptotic cells (Whelan et al, 2012). In zebrafish embryos, *esco2* depletion resulted in Caspase 8 activation that was temporally limited (Monnich et al, 2011). *Esco2* depletion also resulted in a 4-fold increase in the number of apoptotic cells in zebrafish embryos and global induction of apoptosis in medaka embryos, but such increases that occur in inviable or failing embryos are plausibly downstream events indirectly coupled to *esco2* effects (Monnich et al, 2011; Morita et al, 2012). Thus, it remains possible that apoptosis is not the major clinically relevant etiologic effect of *esco2* mutation in RBS patients, especially since apoptosis is not a feature of CdLS cells (Tonkin et al, 2004; Castronovo et al, 2009; Revenkova et al, 2009). I hypothesize that the transcriptional deregulation that arises from *ESCO2* mutations may be the underlying etiologic basis for the developmental abnormalities of RBS - upon which are overlaid cohesion defects, mitotic failure and apoptosis.

Currently, mutation of *ESCO2* represents the sole etiologic agent of the severe developmental disorder Roberts Syndrome (RBS) in humans (Vega et al, 2005). I posit that a second revelation from this work is that *Esco2* may be an upstream regulator of Cx43 function in zebrafish regenerating fins. For instance, *esco2* depletion not only reduces *cx43* expression, but also expression of *sema3d* and *hapln1a*, two genes in the bone growth signaling pathways that rely upon Cx43. Conversely, genes that appear independent of Cx43, such as *shh*, *spry4* and *mps1* were not reduced in *Esco2* knockdown regenerating fins. Notably, the spatial and temporal expressions of *esco2* and *cx43* are nearly identical within the regenerating fin (Iovine et al, 2005). Moreover, the demonstration that overexpression of *cx43* rescues *esco2*-dependent skeletal phenotypes strongly suggests that *Esco2* and Cx43 function in a common pathway. If this model is correct that *Esco2*-dependent expression of Cx43 is an important factor in human development, then *cx43* mutation should similarly manifest developmental abnormalities. In fact, mutations of human *CX43* cause Oculodentodigital dysplasia (ODDD), a malady that includes craniofacial dysmorphias, distal limb skeletal growth defects and abnormal eye and teeth development (Paznekas et al, 2003; Musa et al, 2009). I note prior studies in which mutation/depletion of either *esco2*, *nipbl* or *rad21* were found to impact a plethora of developmentally relevant genes, including *CX43/GJA1* – observations that helped to inform the current work (Monnich et al, 2011; Kawauchi et al, 2009). My findings suggest that *Esco2* function may be coupled to a Cx43-dependent signaling pathway previously shown to directly promote proper development. Based on these results, I suggest that ODDD could be a mild form of cohesinopathies.

Conservatively, this work is consistent with a model that Esco2 regulates the expression of *cx43* and its downstream targets (i.e. *sema3d* and *hapln1a*), thereby influencing growth and skeletal patterning (Figure 2.13). Future experiments to test this model include measuring *cx43* expression level in RBS patient cells and directly assessing *esco2* localization/regulation of the *cx43* promoter. Alternatively, the impact of Esco2 on the skeleton may occur through its roles in DNA damage repair, DNA replication fork progression, chromosome compaction or ribosome maturation/assembly (Skibbens et al, 1999; Skibbens et al, 2010; Gard et al, 2009; Bose et al, 2012; Terret et al, 2009; Unal et al, 2004; Strom et al, 2004; Gerton, 2012; Skibbens et al, 2013).

## 2.6 Figures

**Figure 2.1: Time course *in situ* hybridization of *esco2* in whole mount regenerating fins.** (A) *esco2* expression in 1 day post amputated (dpa) regenerating fin was largely not detectable. (B) *esco2* expression in 3 dpa regenerating fin was strongly detected at the distal end and (C) began to gradually decline in 5 dpa regenerating fin. (D) Expression of *esco2* was reduced in regenerating fin by 8 dpa. The amputation plane is indicated by a solid line except in 8 dpa regenerating fin (panel D), where it is out of the field of view. Scale bar is 50  $\mu\text{m}$ .

**Figure 2.2: *In situ* hybridization of *esco2* in fin cryosections.** (Left) Cryosection from a whole mount wild-type (WT)-5 dpa *in situ* hybridized fin showing tissue specific expression of *esco2* mRNA within the blastema compartment. (Right) *In situ* hybridization was completed on a WT-5 dpa fin cryosection showing a similar pattern of *esco2* expression localized specifically at the blastemal region. Arrows indicate *esco2* expression at blastema. b- blastema, e- epidermis, m- mesenchyme. Scale bar is 50  $\mu$ m.

**Figure 2.3: Timeline of experimental procedure.** Fins were amputated at 50% level and allowed to regenerate for 3 days. At 3 dpa, either gene-targeted morpholino or a control morpholino (MO) was injected to one half of the regenerating fin, immediately followed by electroporation on both sides. After 24 hours, 1 day post electroporation (1 dpe/4 dpa), the fins were evaluated by fluorescence microscopy to confirm MO uptake. The fins were harvested at 1 dpe/4 dpa for histone-3-phosphate (H3P) assay, Terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay, in situ hybridization (ISH), and fin lysate preparation for protein expression by western blot and RNA extraction for quantitative real time PCR (qRT-PCR). Note that for protein lysates and for qRT-PCR, all fin rays across the fin were injected with morpholino and electroporated prior to harvesting at 1 dpe/4 dpa. For 5-bromo-2'-deoxyuridine (BrdU) labeling the MO-injected fins were allowed to swim in 50 $\mu$ g/ml of BrdU water for 5 minutes at 1 dpe/4 dpa and harvested on the same day. For regenerate length and segment length analysis fins were allowed to regenerate longer and were calcein stained at 4 dpe/7 dpa. For each experiment at least 6-8 fish were used per trial and at least 3 independent trials were performed.

**Figure 2.4: Morpholino mediated *Esco2* knockdown phenotypes include reduction in regenerate length and bone segment length.** (A) Representative images showing decreased regenerate length in *esco2* morpholino (MO) injected half compared to the uninjected (UN) half of the same fin. (B) Representative images showing similar levels of regeneration in fins injected with *esco2* mismatch (MM) MO compared to the UN half of the same fin. The red line indicates the amputation plane. Arrows indicate the distance from the amputation plane to the distal end of the 3<sup>rd</sup> fin ray. (C) Representative images of calcein stained segments of the 3<sup>rd</sup> fin ray show shorter bone segments in MO-injected fin half compared to the UN half of the same fin. (D) Representative images of calcein stained segments of the 3<sup>rd</sup> fin ray of MM-injected and UN fins reveal bone segments of similar lengths. For all experiments 6-8 fish were used per trial and at least 3 independent trials were performed. The MO/MM was injected/electroporated in 3 dpa fins and was allowed to regenerate for 4 days. For regenerate length and segment length measurements the fins were calcein stained at 4 dpe/7 dpa. For calcein staining, fish were allowed to swim for 10 minutes in 0.2% calcein (pH 7) at room temperature followed by fresh system water for another 10 minutes. (E) Graph reveals significant reduction (\*) in regenerate length in MO treated fins compared to UN fins. Regenerate length of MM treated fins and UN fins show no significant differences in length. (F) Graph shows significant reduction (\*) in segment length between MO treated fins and UN fins. The segment length of MM treated fins and UN fins show no significant difference. Student's t-test was used for determining statistical significance where  $p < 0.05$ . Error bars represent standard error. Scale bar is 50  $\mu\text{m}$ .

**Figure 2.5: The Esco2 antibody is specific and MO-mediated Esco2 knockdown results in decreased levels of Esco2 protein.** (A) Western blot of bacterial lysates

expressing either GST-Esco2 or GST. Lanes 1 and 4 are lysates of induced GST-Esco2. Lanes 2 and 5 are lysates of uninduced GST-Esco2. Lanes 3 and 6 are lysates of induced GST. When probed with either the anti-Esco2 antibody or an anti-GST antibody, a major protein band of the predicted size of 94 kDa (indicated by an arrowhead) is detected in the induced GST-Esco2 lysates (lanes 1 and 4), and not in the uninduced GST-Esco2 lysates (lanes 2 and 5). Additional bands below 94 kD likely represent proteolysis of GST-Esco2. The anti-Esco2 antibody does not detect GST alone, which has a molecular weight of 26 kD (compare lanes 3 and 6). (B) Two volumes of bacterial lysates expressing GST-Esco2 were loaded in two identical gels. Pre-incubation of the anti-Esco2 antibody with the Esco2 peptide (competed lanes a\* and b\*) significantly reduced the antibody binding compared to non-competed antibody (lanes a and b). The 94 kDa bands are marked (arrowhead). (C) Western blot reveals that anti-Esco2 antibody detects a major protein band at 68 kDa from fin lysate prepared from mismatch (MM) control morpholino injected fins and Esco2 knockdown (MO) fins (1 dpe/4 dpa). The blot confirms the reduction of Esco2 protein in the knockdown lysate (MO) compared to the control lysate (MM). The presence of additional bands in the fin lysates may be due to modification or degradation. Tubulin was used as a loading control. The single band marked was used for relative band intensity analysis using the gel analysis tool (ImageJ software). Similar findings were observed in each of three trials.

**Figure 2.6: Role of *esco2* in cell proliferation.** (A) (Top) Representative images of BrdU-positive cells in uninjected (UN) and *esco2*-MO injected (MO) fins. (Bottom) Representative images of BrdU-positive cells in uninjected (UN) and MM injected fins. Briefly, the MO/MM was injected/electroporated in 3 dpa fins and the next day (1 dpe/4 dpa) the fish were allowed to swim in 50 $\mu$ g/ml BrdU water for 5 mins and then harvested. For all the experiments at least 6-8 fins were used per trial and at least 3 independent trials were performed. The arrow indicates the span of the BrdU-positive cells from the tip of the 3<sup>rd</sup> fin ray (a) and the bracket indicates total regenerate length of the 3<sup>rd</sup> fin ray (b) The amputation plane is shown by a horizontal line. (B) Graph shows the significant reduction (\*) in a/b ratio of BrdU-positive cells in MO injected fins compared to the UN fins. The difference between the MM treated fins and the UN fins is not significantly different. Student's t-test was used for determining statistical significance where  $p < 0.05$ . Error bars represent standard error. Scale bar is 100  $\mu$ m. (C) (Top) Representative images of H3P-positive cells in uninjected (UN) and *esco2*-MO injected (MO) fins. (Bottom) Representative images of H3P-positive cells in uninjected (UN) and MM injected fins. The arrows indicate single H3P-positive cells. At least 6-8 fins were used per trial and 3 independent trials were performed. The MO/MM was injected in 3 dpa fins and harvested at 1 dpe/4 dpa. H3P- positive cells were counted by eye from within the distal-most 250 $\mu$ m of the 3rd fin ray as previously established. (D) Graph shows the significant reduction (\*) in the average number of H3P-positive cells in MO injected fins compared to the UN fins. The difference between the MM treated fins and the UN fins is not significantly different. Student's t-test was used for statistical analysis where  $p < 0.05$ . Error bars represent standard error. Scale bar is 50  $\mu$ m.

**Figure 2.7: Role of *esco2* in programmed cell death.** Representative bright-field image (A) and TUNEL-positive cells (B) in *esco2*-MO injected fin. Representative bright-field image (C) and TUNEL-positive cells (D) in MM injected fins. At least 6-8 fins were used per trial and 3 independent trials were performed. The MO/MM was injected in 3 dpa fins and harvested at 1 dpe/4 dpa. TUNEL-positive cells were counted by eye from within the distal-most 250 $\mu$ m of the 3<sup>rd</sup> fin ray. The amputation plane is shown by a horizontal line and \* indicates the individual fin rays. High levels of TUNEL-positive cells located at the amputation plane serve as an internal control for staining. The box represents the area used to count the cells. (E) Graph shows similar average numbers of TUNEL-positive cells in either MO injected fins or the MM injected fins, compared to the UN fins. Student's t-test was used for determining statistical significance where  $p < 0.05$ . Error bars represent standard error. Bracketed comparisons were not significant. Scale bar is 50  $\mu$ m.

**Figure 2.8: Expression of *esco2* mRNA in wild-type (WT) and *short fin* (*sof*<sup>b123</sup>) fins by whole mount *in situ* hybridization.** WT and *sof*<sup>b123</sup> fins were amputated at 50% level and allowed to regenerate for 5 days. At 5 dpa the fins were harvested. At least 6-8 fins were used per trial and 3 independent trials were performed. (Left) Whole mount *in situ* hybridization (ISH) on WT-5 dpa regenerating fin showing *esco2* expression. (Right) Whole mount ISH on *sof*<sup>b123</sup>-5 dpa regenerating fins shows similar expression levels of *esco2*. The brackets represent the zone of *esco2* expression. Scale bar is 50  $\mu$ m.

**Figure 2.9: *In situ* hybridization on morpholino mediated *Esco2* knockdown fins shows reduced levels of *cx43* expression.** The MO/MM was injected in 3 dpa fins and fins were harvested at 1 dpe/4 dpa. Black lines identify the amputation plane unless it is out of the field of view (i.e. as occurs in most of the higher magnification images). The fin in panel A appears curved since there was less growth on the *Esco2* knockdown side compared with the uninjected side. (A) (Top) Representative image of a fin with *Esco2* knockdown side (*esco2* MO) showing decreased staining of *cx43*, compared to the uninjected side (UN). Bottom left- Higher magnification of the knockdown side (MO) of the same fin (fin rays from top image marked by \*) showing reduced *cx43* expression. (Bottom right) Higher magnification of the uninjected side (UN) of the same fin (fin rays from top image marked by + showing robust *cx43* expression. (B) (Top) Representative image of a fin microinjected with *esco2*-MM in one half and the other side uninjected (UN) reveal similar levels of *cx43*. (Bottom left) Higher magnification of the *esco2*-MM injected side (MM) of the same fin (fin rays from top image marked by \*) showing *cx43* expression. (Bottom right) Higher magnification of the uninjected side (UN) of the same fin (fin rays from top image marked by + showing similar *cx43* expression levels. Scale bar is 100  $\mu$ m.

**Figure 2.10: *cx43* and *cx43*-dependent target genes are reduced following Esco2 knockdown.** The fold difference values from qRT-PCR are shown. A fold difference of 1 indicates no change with respect to standard MO treated fins. Three independent Esco2 knockdown (KD) samples were prepared. Each sample was tested in duplicate (trials 1-3) for *cx43*, *sema3d*, *hapln1a*, *shh*, *spry4* and *mps1*, and compared to the internal reference gene. Circles represent the individual trials and solid circles represent the averages.

**Figure 2.11: Upregulation of both *cx43* mRNA and Cx43 protein in regenerating fins of the transgenic line treated for heat shock.** (A) Expression of *cx43* mRNA in transgenic *hsp70:miR-133sp<sup>pd48</sup>*-positive (Tg+HS+) and *hsp70:miR-133sp<sup>pd48</sup>*-negative (Tg-HS+) fins by whole mount ISH. The Tg+HS+ fins show a higher expression of *cx43* mRNA compared to Tg-HS+ fins. The brackets mark the zone of *cx43* expression in each fin ray and the horizontal line represents the amputation plane. Scale bar is 50  $\mu$ m. (B) Western blot reveals a 50% upregulation of Cx43 protein levels in fin lysates of Tg+HS+ compared to Tg-HS+. Tubulin was used as a loading control. The bands marked were used for relative band intensity analysis using the gel analysis tool (ImageJ software). (C) Expression of *esco2* mRNA in transgenic *hsp70:miR-133sp<sup>pd48</sup>*-positive (Tg+HS+) and *hsp70:miR-133sp<sup>pd48</sup>*-negative (Tg-HS+) fins by whole mount ISH. Tg+HS+ and Tg-HS+ fins show similar expression level of *esco2* mRNA. The brackets mark the zone of *esco2* expression in each fin ray and the horizontal line represents the amputation plane. Scale bar is 50  $\mu$ m. (D) Western blot reveals the Esco2 protein expression is nearly similar (90%) in fin lysates of Tg+HS+ and Tg-HS+. Tubulin was used as a loading control. The single band marked was used for relative band intensity analysis using the gel analysis tool (ImageJ software).

**Figure 2.12: Overexpression of *cx43* rescues *Esco2* knockdown phenotypes.** (A) Figure depicting the timeline of fin amputation, morpholino injection and electroporation, heat shock, and data analysis. The 3 groups included in this experiment were Tg+HS- (transgenic *hsp70:miR-133sp<sup>pd48</sup>*-positive, heat shocked), Tg+HS+ (transgenic *hsp70:miR-133sp<sup>pd48</sup>*-negative, heat shocked) and Tg+HS- (transgenic *hsp70:miR-133sp<sup>pd48</sup>*-positive, not heat shocked). Briefly, fins from all three groups were amputated at 50% level and allowed to regenerate for 3 days. At 3 dpa, morpholino was injected to one half of the regenerating fin tissue, immediately followed by electroporation on both sides. After an interval of 4 hours fish receiving heat shock were shifted to 37°C for 1 hour. Induction of the transgene expression upon heat shock was confirmed after 24 hours by screening for GFP-positive fins in the Tg+HS+ group. The control groups (Tg+HS+ and Tg+HS-) were negative for GFP expression. For ISH experiments, the fins were harvested at 1 dpe/4 dpa. For measurement of regenerate length and segment length fins were calcein stained at 4 dpe/7 dpa. For each experiment at least 6-8 fish were used per trial and at least 3 independent trials were performed (B) Graph reveals significant (\*) rescue of *esco2*-dependent segment length defects in heat shocked *miR-133sp<sup>pd48</sup>*-positive *Esco2* knockdown fins (Tg+HS+) compared both to heat shocked transgene-negative (Tg+HS+) and to *miR-133sp<sup>pd48</sup>*-positive with no heat shock (Tg+HS-). Measurements from the injected side and the uninjected side of the same fin were used to calculate percent similarity and the average was calculated for each group. Note that a percent similarity of 100% indicates no difference between the knockdown side and the control sides of the fin. Student's t-test was used for determining statistical significance where  $p < 0.05$ . Error bars represent standard error. (C) Graph reveals significant (\*) rescue of *esco2*-dependent regenerate length defects in heat shocked *miR-133sp<sup>pd48</sup>*-positive *Esco2* knockdown fins (Tg+HS+) compared both to heat shocked transgene-negative (Tg+HS+) and to *miR-133sp<sup>pd48</sup>*-positive in the absence of heat shock (Tg+HS-).

**Figure 2.13: New model depicts the connection between Esco2 and Cx43 skeletal patterning pathway during fin regeneration.** Proposed pathway for Esco2 regulation of *cx43* expression levels and genes downstream of *cx43*. Esco2 may have additional targets.

## 2.6 Table

Gene	Average $C_{T(esco2 \text{ KD})}$	Average $C_T$ (keratin)	$\Delta C_T$ <i>esco2</i> KD -keratin <sup>a</sup>	$\Delta C_T$ <i>esco2</i> MM -keratin <sup>a</sup>	$\Delta \Delta C_T$ $\Delta C_{T(MO)}$ - $\Delta C_T$ (MM) <sup>b</sup>	Fold Difference relative to MM <sup>c</sup>
<i>cx43</i>	23.31 ± 0.11	17.14 ± 0.15	6.16 ± 0.19	5.21 ± 0.14	0.95 ± 0.24	0.51 (0.43 - 0.61)
<i>sema3d</i>	24.25 ± 0.15	17.25 ± 0.07	7.0 ± 0.16	6.05 ± 0.12	0.94 ± 0.21	0.52 (0.44 - 0.6)
<i>hapln1a</i>	24.43 ± 0.05	18.09 ± 0.04	6.34 ± 0.07	5.57 ± 0.42	0.85 ± 0.42	0.58 (0.43-0.78)
<i>mps1</i>	22.27 ± 0.08	17.72 ± 0.08	4.55 ± 0.12	4.47 ± 0.34	-0.08 ± 0.36	0.94 (0.73 - 1.21)
<i>shh</i>	22.7 ± 0.1	19.51 ± 0.05	3.24 ± 0.11	3.53 ± 0.14	-0.28 ± 0.18	1.21 (1.07-1.38)
<i>spry4</i>	23.3 ± 0.08	19.35 ± 0.1	3.91 ± 0.13	4.45 ± 0.31	-0.54 ± 0.34	1.45 (1.14-1.85)

**Table 2.1: Quantitative RT-PCR confirms changes in gene expression**

a. The  $\Delta C_T$  value is determined by subtracting the average Keratin  $C_T$  value from the average Gene  $C_T$  value. The standard deviation of the difference is calculated from the standard deviations of the gene and Keratin values using the Comparative Method.

b. The calculation of  $\Delta \Delta C_T$  involves subtraction by the  $\Delta C_T$  calibrator value. This is subtraction of an arbitrary constant, so the standard deviation of  $\Delta \Delta C_T$  is the same as the standard deviation of the  $\Delta C_T$  value.

c. The range given for gene relative to MM is determined by evaluating the expression:  $2^{-\Delta \Delta C_T}$  with  $\Delta \Delta C_T + s$  and  $\Delta \Delta C_T - s$ , where  $s$  = the standard deviation of the  $\Delta \Delta C_T$  value.

## **CHAPTER 3**

### **Cohesin mediates Esco2-dependent transcriptional regulation in zebrafish regenerating fin model of Roberts Syndrome**

### 3.1 Abstract

Robert syndrome (RBS) and Cornelia de Lange syndrome (CdLS) are human developmental disorders characterized by craniofacial deformities, limb malformation, and mental retardation. These birth defects are collectively termed cohesinopathies as both arise from mutations in cohesion pathway genes. The mechanism that underlies RBS, however, remains unknown. Previously, I used the clinically relevant *CX43* to demonstrate a transcriptional role for *Esco2*. In this chapter, I show that morpholino-mediated knockdown of *Smc3* perturbs zebrafish bone and tissue regeneration, producing similar results to those previously reported for *Esco2* knockdown. Additionally, *Smc3* knockdown also reduces *cx43* expression. Importantly, *Smc3*-dependent bone and tissue regeneration defects are rescued by transgenic *cx43* overexpression, providing evidence that *Smc3* directly contributes to RBS-type phenotypes in the regenerating fin model produced by *Esco2* knockdown. Moreover, chromatin immunoprecipitation (ChIP) assays revealed that *Smc3* binds to a discrete region of the *cx43* promoter, suggesting that *Esco2* exerts transcriptional regulation of *cx43* through modification of *Smc3* bound to the *cx43* promoter. These findings unify RBS and CdLS as transcription-based maladies.

**This work is currently under the revision process in *Biology Open*: Banerji, R, Iovine, M.K. and Skibbens, R.V, 2017. Cohesin mediates *Esco2*-dependent transcriptional regulation in zebrafish regenerating fin model of Roberts syndrome. Funding: Nemes Fellowship and Lehigh University Faculty Innovation Grant.**

### 3.1 Introduction

Roberts syndrome (RBS) is a multi-spectrum developmental disorder characterized by severe skeletal deformities resulting in craniofacial abnormalities, long-bone growth defects and mental retardation (Van den Berg and Francke, 1993; Vega et al., 2005). Infants born with severe forms of RBS are often stillborn and even modest penetrance of RBS phenotypes lead to significantly decreased life expectancy (Schule et al., 2005). Cornelia de Lange Syndrome (CdLS) patients exhibit similar phenotypes to RBS patients that include severe long-bone growth defects, missing digits, craniofacial abnormalities, organ defects and severe mental retardation (Liu and Krantz, 2009; Mannini et al., 2010). Collectively, RBS and CdLS are termed cohesinopathies as they arise due to mutations in cohesion genes, most of which were originally identified for their role in sister chromatid tethering reactions (termed cohesion) (Vega et al., 2005; Schule et al., 2005; Gordillo et al., 2008; Krantz et al., 2004; Musio et al., 2006; Tonkin et al., 2004; Deardorff et al., 2007; Deardorff et al., 2012a, Deardorff et al., 2012b). Cohesins are composed of two structural maintenance of chromosome (SMC) subunits, SMC1A and SMC3, and several non-SMC subunits that include RAD21 (Mcd1/Sccl1), SA1, 2 (stromal antigen/Sccl3/Irr1) and PDS5. At least a subset of cohesion subunits form rings that appear to topologically entrap DNA (Jeppsson et al., 2014; Dorsett, 2016; Marston, 2014).

RBS is an autosomal recessive disease that arises due to loss of function mutations in the *ESCO2* gene that encodes an N-acetyltransferase (Ivanova and Ivanov, 2002; Vega et al., 2005). *ESCO2/EFO2* (and *ESCO1/EFO1* paralog) are the human orthologues of the *ECO1/CTF7* first identified in budding yeast (Skibbens et al., 1999; Toth et al., 1999; Bellows et al., 2003; Hou and Zou, 2005). All ESCO/EFO family N-acetyltransferases

modifies the SMC3 cohesin subunit (Zhang et al., 2008; Unal et al., 2008; Rolef Ben-Shahar et al., 2008). ESCO2 plays an essential role in sister chromatid cohesion during S phase and ensures proper chromosome segregation during mitosis. In contrast, CdLS arises due to autosomal dominant mutations in cohesin subunits (*SMC1A*, *SMC3* and *RAD21*) and cohesin auxiliary factors (*NIPBL* and *HDAC8*) (Krantz et al., 2004; Tonkin et al., 2004; Schule et al., 2005; Musio et al., 2006; Deardorff et al., 2007; Deardorff et al., 2012a, Deardorff et al., 2012b; Gordillo et al., 2008; Yuan et al., 2015). NIPBL/Scs2 and MAU2/Scs4 heterodimer complex are required for cohesin ring opening/closing reactions that loads cohesins onto DNA (Dorsett and Merckenschlager, 2013; Skibbens, 2016).

Extensive research provides fascinating evidence that cohesin functions beyond sister chromatid cohesion (*trans*-tethering that brings together two DNA molecules). Cohesins also participate in various *cis*- tethering events such as transcriptional regulation via looping and chromosome condensation (Dorsett and Merckenschlager, 2013). Intriguingly, cohesins form both *cis* and *trans*- DNA tethers throughout the genome and throughout the cell cycle, a circumstance that has hampered efforts to understand the specific structures and functions, when mutated, which contribute to the molecular etiology of cohesinopathies. For instance, work from various model systems strongly suggest that CdLS arises through transcriptional deregulation that involves mostly *cis*-DNA tethers formed during G1 portion of the cell cycle. In contrast, a predominant view is that RBS arises through *trans*-tethering defects that result in mitotic failure and loss of progenitor stem cells through apoptosis (Monnich et al., 2011; Morita et al., 2012; Percival et al., 2015). More recent evidence, however, is consistent with an

emerging model that transcriptional deregulation may underlie RBS as well as CdLS (Banerji et al., 2016; Xu et al., 2013; Xu et al., 2014).

The zebrafish regenerating caudal fin is a valuable model system for studies related to skeletal morphogenesis (Iovine, 2007; Ton and Iovine, 2013). Advantages of the adult fin include its simple structure, accessibility, and its capacity for epimorphic regeneration. Furthermore, the regenerating fin eliminates any potentially confounding effects of embryonic lethality observed during development upon cohesin gene knockdown (Monnich et al., 2011; Morita et al., 2012). In the previous chapter (also published as Banerji et al., 2016), I report on a novel regenerating fin model of RBS and documented the role of *esco2* in skeletal and tissue regrowth. Importantly, I revealed that *Esco2* is critical for Connexin43 (*cx43*) expression. Cx43 comprises gap junctions which confer direct communication between cells through channels that allows small signaling molecules (<1000 Da) to pass (Goodenough et al., 1996). CX43 function is conserved among vertebrates, is the most abundant connexin in bone cells, and is important for skeletal development such that *CX43* mutations lead to the skeletal disorder Oculodentodigital dysplasia (ODDD) in humans and mice (Paznekas et al., 2003; Flenniken et al., 2005; Jones et al., 1993). In zebrafish, mutations in *cx43* cause *short fin* (*sof<sup>b123</sup>*), phenotypes that include reduced fin length, reduced bone segment length, and reduced cell proliferation (Iovine et al., 2005). Here, I provide evidence that *Smc3* knockdown recapitulates both *Esco2* and *Cx43* knockdown phenotypes (i.e. decreased bone segment and tissue regrowth). Critically, *smc3* is required for *cx43* expression. Moreover, I mapped *Smc3* binding within the *cx43* promoter, consistent with the model that *Smc3* directly impacts *cx43* expression. These findings provide new insight

regarding the underlying molecular mechanism of RBS, indicating that Esco2 activated Smc3 binds to clinically relevant skeletal regulatory genes.

### **3.3 Materials and methods**

#### **Statement on the Ethical Treatment of Animals**

This work was performed strictly according to the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. Lehigh's Institutional Animal Care and Use Committee (IACUC) approved the protocols performed in the manuscript (Protocol identification # 190, approved 05/19/16). Lehigh University's Animal Welfare Assurance Number is A-3877-01. All experiments were performed to minimize pain and discomfort.

#### **Housing and Husbandry**

Zebrafish (*Danio rerio*) were housed in a re-circulating system built by Aquatic Habitats (now known as Pentair). The fish room has a 14:10 light: dark cycle with tightly regulated room temperature ranging from 27 to 29°C (Westerfield, 1993). Monitoring of the water quality is done automatically to maintain conductivity of 400–600 µs and pH in the range of 6.95–7.30. A biofilter is used to maintain nitrogen levels and a 10% water change occurs daily. Sequential filtration of recirculating water was carried out using pad filters, bag filters, and a carbon canister before circulating over ultraviolet lights for sterilization. Fish feeding schedule was as follows: fed three times daily, once with brine shrimp (hatched from INVE artemia cysts) and twice with flake food (Aquatox AX5) supplemented with 7.5% micropellets (Hikari), 7.5% Golden Pearl (300–500 micron, Brine Shrimp direct), and 5% Cyclo-Peeze (Argent).

### **Zebrafish Strains and fin amputations**

Both wild-type (C32) and *Tg (hsp70: miR-133sp<sup>pd48</sup>)* (Yin et al., 2012) *Danio rerio* animals were used. Males and females from 6 months-1 year of age were included. All procedures involving caudal fin amputations, fin regeneration, and harvesting were done as previously described (Banerji et al., 2016). Briefly, 0.1% tricaine solution was used for fish anaesthetization and their caudal fin rays amputated at 50% level using a sterile razor blade. Regenerating fins were harvested at the required time points and fixed in 4% paraformaldehyde (PFA) overnight at 4°C. The fixed fins were dehydrated in methanol (100%) and stored at 20°C until further use.

### **Morpholino-mediated gene knockdown in regenerating fins**

The morpholinos (MOs) used were all fluorescein-tagged and purchased from Gene Tools, LLC. The sequences for MOs are as follows: (MO1) *smc3*-ATG blocking MO: 5'-TGTACATGGCGGTTTATGC -3', (MO2) *smc3*-splice blocking MO: 5'-GCGTGAGTCGCATCTTACCTGTTTA-3', *esco2* –MO and Standard Control MO (Std-MO) from Banerji et al., 2016. MOs were reconstituted to a final concentration of 1 mM in sterile water. Microinjection and electroporation procedures were carried out as described in the previous studies (Banerji et al., 2016).

### **Regenerate Length, segment length, and H3P analyses**

MO injected fins were calcein stained at 4 dpe/7 dpa and regenerate length and segment length was determined as described (Du et al., 2001; Banerji et al., 2016). For detection

of mitotic cells, histone-3-phosphate (H3P) assay was performed on fins harvested at 1 dpe/4 dpa as described (Banerji et al., 2016).

### **RNA extraction and RT-PCR analysis on regenerating fins**

RT-PCR analysis was performed on total mRNA extracted from 1 dpe/4 dpa harvested fins that were either injected with *smc3* splice blocking MO (MO2) or Std-MO injected. Trizol reagent (Gibco) was used to extract mRNA from minimum of 8-10 fins. For making cDNA, 1 mg of total RNA was reverse transcribed with SuperScript III reverse transcriptase (Invitrogen) using oligo (dT) primers. Two pairs of primers were used for testing the splicing efficiency. The control primer pair (C1-C2) was designed to amplify a portion of the exon 1 of *smc3* mRNA whereas the targeting primer pair (P1-P2) was designed to amplify the exon1 along with a portion of the intron1. The sequences of the control primers are as follows: C1 (forward primer) 5'-GACTGTTATGTCTTTTGCGTG-3' and C2 (reverse primer) 5'-GCGGTTTATGCACAAAACACT-3'. The sequences of the targeting primers are as follows: P1 (forward primer) 5'-GGAGGAGGGTGTTTAATTCAGC-3' and P2 (reverse Primer) 5'-GCTTCGAAAGCCTTGAATAATGAC-3'.

### **RNA probe preparation for in situ hybridization on whole-mount /cryosectioned fin**

The *cx43* template was made as described (Iovine et al., 2005). The *smc3* template was generated using gene-specific primers (Forward primer 5'-CAAAGTGTGGTCGATCCCTTCAGC and reverse primer 5'-TAATACGACTCACTATAGGGGCTTCTCTTCAATCTTCT-3'). The RNA

polymerase T7 (RT7) binding site is highlighted in bold for the reverse primer.

Digoxigenin-labelled RNA probes were generated and whole mount/cryosection in situ hybridization was completed as previously described (Banerji et al., 2016).

### **Transgenic overexpression of *cx43***

*Tg(hsp70:miR-133sp pd48)* denoted as transgene-positive (Tg+) and their siblings denoted as transgene-negative (Tg-) were used in the heat shock experiment as previously described (Banerji et al., 2016). Knocking down miR-133 (which targets *cx43* for degradation) via the 'sponge' transgene (three miR-133 binding sites) results in the increase of *cx43* levels (Yin et al., 2012).

### **Morpholino-mediated protein knockdown via electroporation in AB9 cells**

AB.9 (ATCC<sup>®</sup> CRL-2298<sup>™</sup>) is a primary fibroblast cell line originating from the zebrafish caudal fins. Once the cells were at 80- 90% confluency in 100 mm dishes (28°C with 5% CO<sub>2</sub>) knockdown procedure was completed (Bhadra et al., 2015). Briefly, the adherent cells were washed with 1X PBS and trypsinized in 0.05% Trypsin-EDTA 1X (Gibco) for 5 min at 28°C. DMEM media supplemented with 15% heat inactivated FBS, antibiotics-antimycotics (Gibco) were added to inactivate the trypsin. The cells were collected by centrifugation at 750 rpm for 5 minutes. The pellet was re-suspended in 1-5ml of HEPES buffer (115mM NaCl, 1.2mM CaCl<sub>2</sub>, 1.2mM MgCl<sub>2</sub>, 2.4mM K<sub>2</sub>PO<sub>4</sub> and 20mM HEPES with pH adjusted to 7.4) and put on ice. MOs were added to 400µl of re-suspended cells in the cuvettes on ice and incubated for 5 minutes. The cells were electroporated at 170V for 6-7 ms using an electroporator (BioRad Gene Pulser X Cell).

Electroporated cells were added to 1ml of fresh media in 60mm culture dishes and incubated at 28°C for 24 hours.

### **Lysate preparation and immunoblotting**

For cell lysate preparation for western blots, AB9 cells were washed in cold PBS and cold lysis buffer (5mM Tris-HCl, 5mM EDTA, 5mM EGTA with pH 7.5) with 100X Halt-TM protease and phosphatase inhibitor cocktail (Thermo Scientific) and 0.6% SDS buffer. A sterile rubber cell scraper (Corning Incorporated, Costar) was used for scraping. A 5ml syringe (Beckton Dickinson) with an 18G needle was used to collect the lysate in a fresh tube and was heated at 100°C for 3 min. A 26G needle (Beckton Dickinson) was used to pass the lysate through at least 3 times. The cell lysates were stored in small aliquots in -80°C. These cell lysates were used to run western blot as described (Hoptak-solga et al., 2008). Cx43, Esco2, Smc3 and Tubulin were detected using anti-Cx43 (1:1000, Hoptak-Solga et al., 2008), anti-Esco2 (1:1000, Banerji et al., 2016), anti-Smc3 (1:1000, Santa Cruz) and anti- $\alpha$ -Tubulin (1:1000, Sigma) respectively. The primary antibody step was followed by incubation in peroxidase-conjugated goat anti-rabbit IgG (1:10,000) for Cx43 and Esco2, peroxidase-conjugated rabbit anti-goat IgG (1:10,000) for Smc3 and peroxidase-conjugated goat anti-mouse IgG (1:10,000) for Tubulin. The ECL chemiluminescent reagent (SuperSignal West Femto Maximum Sensitivity Substrate, Pierce Rockford, IL) and X-ray films were used for signal detection. For measurement of band intensities and the percent change calculation, the Image J software was used. Relative pixel densities of gel bands were measured using the gel analysis tool in ImageJ software as previously described (Bhadra and Iovine, 2015).

### **Immunofluorescence on AB9 cells**

Poly-L-lysine cover glasses were used for seeding the cells as previously described (Bhadra et al., 2015). Once cells were 70 -80% confluent, they were washed cold PBS and fixed with 4% PFA for 30 min at room temperature. This was followed by washes in PBS (3X for 5 minutes each), permeabilization with 0.2% triton for 10 minutes, followed by multiple washes in PBS. Blocking was done using 1% BSA for 1 hr at room temperature. The cover slips were incubated with the primary antibody (see above) overnight at 4°C (in a covered chamber surrounded with damp Kim wipes). Cells were incubated with the secondary antibody for 1 hour at room temperature (protected from light). The secondary antibodies used were as follows: anti-rabbit Alexa 488 or 568 (1:200, Invitrogen), anti-mouse Alexa 488 or 568 (1:200, Invitrogen). DAPI (1:1000, MP Biomedicals, LLC.) labels the nucleus. Cells were mounted with Vectashield (Vector Laboratories) and examined with Nikon Eclipse TE2000-U at 40X or 60X.

### **Chromatin Immunoprecipitation (ChIP)**

ChIP protocol was performed on AB9 cells using the High-Sensitivity ChIP kit (Abcam, ab185913) according to manufacturer's instruction. The procedure for monolayer or adherent cells was followed with few modifications. Briefly, cells were grown to 80%-90% confluence on 100 mm dishes (around 4-6 dishes per round of ChIP), trypsinized and centrifuged at 1000 rpm for 20 minutes. The pellet was washed with 10 mL of 1X PBS and again centrifuged at the same speed and time. For cross-linking, 9 ml DMEM medium-containing formaldehyde (final concentration of 1%) was added to the cells and incubated at room temperature for 10 minutes on a rocker. After 10 minutes 1.25 M

Glycine solution was added and centrifuged at 1000 rpm for 20 minutes followed by a washing step with 10 mL of ice cold 1X PBS. After another round of centrifugation, Lysis Buffer with protease inhibitor was used to re-suspend the cell pellet (200 $\mu$ L/1x10<sup>6</sup> cells) and incubated on ice for 30 minutes with periodic vortexing. The solution was centrifuged at 3000 rpm for 20 minutes and the chromatin pellet re-suspended with the ChIP Buffer supplied in the kit (100  $\mu$ l/1x10<sup>6</sup> cells). Chromatin was sheared using a tip sonicator (Branson sonifier cell disrupter 200) with a 2.4 mm tip diameter microprobe, (Qsonica P-3) set to 25% power output. Sonication was carried out in 3-4 pulses of 10-15 seconds each, followed by 30-40 seconds rest on ice between each pulse. The sonicated chromatin was centrifuged at 12,000 rpm at 4°C for 10 minutes and stored at -20°C. A small amount of chromatin solution was used for DNA extraction in order to verify the size of the sheared DNA before starting the immunoprecipitation procedure (100-700 bp with a peak size of 300 bp). Antibody binding to assay wells and ChIP reactions was performed according to the manufactures instructions. Antibodies used were anti-IgG (kit) and anti-Smc3 (Santa Cruz) with a concentration of 0.8  $\mu$ g/well for both antibodies. The sealed strip wells with the respective antibodies and Antibody Buffer (kit) were incubated for 90 mins at room temperature on an orbital shaker. ChIP reaction was set up according to the low abundance target criteria (details provided in the protocol booklet) overnight at 4°C on an orbital shaker. Next day the wells were washed with Wash buffer (kit) and DNA release buffer and cross-links were reversed (according to the manual). The released DNA was used in PCR or qRT-PCR reactions.

### **ChIP primer design and qPCR**

The zebrafish *cx43* promoter sequence was obtained from the BAC clone (DKEY-261A18). Overlapping 31 primer pairs were designed spanning the entire 6.7 kb region of the *cx43* promoter (Table S1). For qRT-PCR analysis, the primers were designed using the Primer Quest tool software from IDT (Table 3.2). Three independent samples were prepared for *ChIP*, and qRT-PCR reactions were performed in duplicate. *ChIP* DNA for non-immune IgG served as the negative control. The templates were a 1:10 dilution following *ChIP* using either IgG or Smc3 antibodies. PCR reactions were set up using SYBR green kit (Qiagen). Analyses of the amplified samples were done using Rotor-Gene 6000 series software (Corbette Research) and the average cycle number ( $C_T$ ) determined for each amplicon. For fold enrichment calculation the *smc3*  $C_T$  values were normalized relative to IgG control values and were represented as delta  $C_T$  ( $\Delta C_T$ ). The fold enrichment was determined using the  $\Delta\Delta C_T$  method ( $2^{-\Delta\Delta C_T}$ ). Statistical significance was determined by one-way ANOVA test ( $P < 0.001$ ) using the MINITAB 17 software.

### **Statistical analysis**

All graphs and error bars were generated using the Microsoft excel (2013) software. For statistical significance calculation, two-tailed unpaired *t*-test was performed using Graphpad software (La Jolla California USA, [www.graphpad.com](http://www.graphpad.com)). Statistical significance was also determined by one-way ANOVA test ( $P < 0.001$ ) using the MINITAB 17 software.

### 3.4 Results

#### Expression of *smc3* in the regenerating fin

*Esco2* is a critical regulator of fin skeletal and tissue regeneration that is required for expression of the developmental signaling factor *cx43* (Banerji et al., 2016). While *Esco2* is essential for modifying the cohesin subunit *Smc3* to produce sister chromatid tethering and high fidelity chromosome segregation, a role for *Smc3* in mediating *Esco2*-dependent RBS-like skeletal and tissue defects remains unknown. To address this gap in knowledge I evaluated *smc3* expression and function during fin regeneration. First, I completed in situ hybridization to monitor the temporal expression of *smc3* mRNA in 1, 3, 5, 8 and 14 days post amputated (dpa) fins. The results reveal that *smc3* mRNA is strongly expressed 3 dpa, similar to *esco2* expression (Figure 3.1A). *smc3* expression decreased by 5 dpa fins and was negligible by 14 dpa (Figure 3.1A). Thus, the *smc3* expression mirrors that of *esco2* - both of which peak in expression at 3 dpa when regeneration is at its peak (Banerji et al., 2016; Lee et al., 2005; Hoptak-Solga et al., 2008).

Expression of *esco2* mRNA is localized to the highly proliferative blastemal compartment of the fin (Banerji et al., 2016). To test whether *smc3* expression is localized similarly to the blastema, I performed in situ hybridization on 3 dpa cryosectioned fins. The results reveal that the expression of *smc3* correlate with *esco2* localization (Figure 3.1B), but that *smc3* also extends to the epidermis, mesenchyme and skeletal precursor cells (Figure 3.1B, left panel). No staining was detected in 3 dpa cryosectioned fin in the absence of the *smc3* probe (Figure 3.1B, right panel). In combination, these studies reveal that *smc3* expression both temporally and spatially

coincides with that of *esco2* expression, consistent with a requirement during the early stage of regeneration specifically in the proliferative blastemal compartment of the regenerating fin.

### **Knockdown of Smc3 results in reduced regenerate length, segment length and cell proliferation**

In my first publication I have reported that *Esco2* is essential for regenerate length, segment length and cell proliferation in the regenerating fins (Banerji et al., 2016). To provide evidence that cohesins may mediate these *Esco2*-dependent effects, I designed two independent non-overlapping MOs that target *Smc3*: one targeting *smc3* ATG (MO1) and the second targeting the first splice site junction (exon1-intron1; e1i1) of *smc3* gene (MO2) (Figure 3.2A). Thus, MO1 blocks translation of *Smc3* whereas MO2 alters the *smc3* pre-mRNA proper splicing. All results were compared to a standard negative control MO (Std-MO) as previously described (Banerji et al., 2016; Bhadra et al., 2015).

I first validated the efficiency of the two *smc3* MOs. MO1 efficiency was tested by monitoring *Smc3* protein levels in AB9 cells transfected with either MO1 or Std-MO (Bhadra et al., 2015). AB9 cells are primary fibroblasts derived from regenerating caudal fins of the adult zebrafish (Bhadra et al., 2015). The results reveal that the *Smc3* protein levels were significantly reduced (60%) in the *Smc3* knockdown lysates compared to the control lysates (Figure 3.2B). To confirm the effectiveness of splice blocking MO2, I performed RT-PCR in 4 dpa regenerating fins. RT-PCR results reveal that intron1 was

retrieved only when fins were injected with MO2 and not when injected with Std-MO (Figure 3.2C).

Using both MOs I carried out microinjection and electroporation as previously described (Govindan et al., 2016; Banerji et al., 2016) (Figure 3.2D). All MOs are tagged with fluorescein, allowing us to validate cellular uptake microscopically 1 day post electroporation (dpe) or 4 dpa. Only MO-positive fins were selected for further experiments. For measurement of regenerate length and segment length, *Smc3* knockdown/Std-MO fins were calcein stained at 4 dpe/7 dpa and measured. To reduce the effect of fin-to-fin variation, I utilized the percent similarity method in which 100% indicates no difference between injected and non-injected sides of the same fin, whereas a value less than 100% indicates differences between the injected and non-injected sides of the same fin (Govindan et al., 2016; Bhadra and Iovine, 2015; Banerji et al., 2016). Quantification of regenerate length was based on the distance from the plane of amputation to the distal end of the 3<sup>rd</sup> fin ray. Quantification of bone segment length was based on measurements obtained from the first segment distal to the amputation plane of the 3<sup>rd</sup> fin ray. The Std-MO injected fins showed a high percent similarity to the uninjected side, indicating that the control MO had no effect on regenerate and bone segment length as expected. In contrast, both MO1 and MO2 showed low percentage of similarities, indicating significant differences between the injected and non-injected sides. Thus *Smc3* is critical for both regenerate length and segment length similar to *Esco2* (Figure 3.3A-D).

*Esco2* knockdown also results in reduced cell proliferation (Banerji et al., 2016). Thus, I next addressed whether the effect of *Smc3* knockdown on both regenerate length

and segment length was based on altered cell proliferation rates. To test this, I quantified the number of mitotic cells by staining for Histone-3 phosphate (H3P) on 1 dpe *Smc3* knockdown (MO1 and MO2) and Std-MO injected fins. The results reveal significant reduction in H3P-positive cells in *Smc3* knockdown fins compared to the control fins (Figure 3.3E, F). Thus, *Smc3*-dependent phenotypes are similar to both *Esco2* and *Cx43*-dependent phenotypes previously reported (i.e. reduced regenerate length, segment length and cell proliferation) (Banerji et al., 2016; Iovine et al., 2005). Having validated *Smc3* knockdown phenotypes using two non-overlapping MOs, all subsequent experiments were performed using a single targeting MO (MO1).

### ***smc3* and *esco2* function together during skeletal regeneration**

*esco2* is critical for *cx43* expression, although the basis for this regulation remains unknown (Banerji et al., 2016). Thus, it became important to determine if *Smc3* knockdown also influences *cx43* expression. I performed whole mount in situ hybridization with *cx43* probe on *Smc3* knockdown fins. Half of the fin was injected with MO1 or Std-MO and the other half was kept uninjected as an internal control. Remarkably, the *Smc3* knockdown side exhibited significantly reduced expression of *cx43* compared to the uninjected side (Figure 3.4A). In contrast, the Std-MO injected side showed no difference in *cx43* expression compared to the uninjected side (Figure 3.4B).

To determine the genetic relationship between *smc3* and, I tested for rescue of *smc3*-MO phenotypes by over expressing *cx43* (Banerji et al., 2016). For this purpose, I used the transgenic line, *Tg(hsp70:miR-133sp<sup>pd48</sup>)* that indirectly over express *cx43* in both regenerating heart and fins (Yin et al., 2012; Banerji et al., 2016). The three groups

of fish for this experiment were as follows: (1) transgene positive and heat shocked (Tg+HS+), (2) transgene negative and heat shocked (Tg-HS+) and (3) transgene positive but not heat shocked (Tg+HS-) (Figure 3.5A). Importantly, three independent heat shock trials revealed that both regenerate length and bone segment length defects otherwise exhibited in Smc3 knockdown were significantly rescued in the Tg+HS+ group (Figure 3.5B). This rescue was specific to transgene activation and was not induced by heat shock alone or in combination with any other group. These findings support an exciting model that Smc3 functions upstream to regulate *cx43* gene expression, similar to *Esco2*.

#### **AB9 cells are suitable for testing the *smc3/esco2-cx43* skeletal pathway**

What is the basis through which both *Esco2* and *Smc3* regulate *cx43* expression? To address this issue, I switched to AB9 fibroblast cell line, that are less complex than regenerating fish fin tissue and previously reported to express Cx43 (Bhadra et al., 2015). I first tested whether AB9 cells also express *Esco2* and *Smc3*. AB9 cells grown on a coverslip were fixed and processed for immunofluorescence. The results show that anti-*Esco2* antibody and anti-*Smc3* antibody co-localize and overlap with the DAPI-stained nuclei (Figure 3.6A). I next tested whether either *esco2*- or *smc3*- similarly regulate Cx43 protein levels as occurs in regenerating fins. Cx43 protein levels were monitored by Western blot in AB9 cells knocked down for either *esco2* MO or *smc3* MO. The results show that *Esco2* or *Smc3* proteins were each reduced using their respective knockdown morpholinos (Figure 3.6B). Critically, Cx43 protein levels also were reduced following either knockdown (Figure 6B). Therefore the AB9 system recapitulates the effect of

Esco2 and Smc3 knockdown in reducing Cx43 expression levels, similar to results obtained in regenerating fins (Banerji et al., 2016).

### **Smc3 directly binds to a specific region of the *cx43* promoter**

It is well established that cohesins bind directly and stabilize DNA-tethering structures required for efficient gene expression (Dorsett, 2016; Merkenschlager and Nora, 2016; Jeppsson et al., 2014). Thus, I hypothesized that Smc3, as a part of the cohesin complex, directly binds to a segment of the *cx43* promoter. The *cx43* promoter is approximately 6.7 kb in length, adjacent to an additional connexin gene (*cx32.2*) that resides upstream of the *cx43* coding sequence (Chatterjee et al., 2005; Figure 3.7A). I assayed Smc3 binding to the *cx43* promoter by performing Chromatin Immunoprecipitation (ChIP) on AB9 cells. I first optimized the ChIP procedure using Smc3 as the target antibody and IgG as the negative control. Since this is the first time that protein binding to the putative *cx43* promoter is investigated, I performed qualitative PCR analysis. I designed 31 primers pairs that, in overlapping fashion, span the entire 6.7 kb promoter (Table 3.1). Positive binding was observed for primers 2-6 (800bp), primer 11 (250bp) and primers 18-28 (1.5kb). In contrast, the negative control (IgG) exhibited little to no binding throughout the promoter length (Figure 3.7A).

To investigate in detail the specific regions of the *cx43* promoter to which Smc3 binds, I next performed qRT-PCR. I designed 5 primer pairs that spanned the Smc3 positive binding regions obtained from the qualitative PCR analysis (p2- p6) and 2 primer pairs as negative controls that fall within zones devoid of Smc3 binding (p1 and p7). The results reveal significant binding of Smc3 specifically within one region (p2) of the *cx43*

promoter (Figure 3.7B). Binding was also observed at p3-p6, but at levels that did not rise to statistically significant levels. The negative controls (p1 and p7) showed negligible binding. These ChIP results provide strong evidence that Smc3 binds directly to the *cx43* promoter.

### 3.5 Discussion

Esco2 mutations are the only known etiologic agent for RBS. Previously, I established Esco2 knockdown in regenerating fin as a powerful system from which to elucidate the molecular basis of RBS. One major revelation is that Smc3 functions in a similar manner as Esco2 during fin regeneration. First, *smc3* mRNA expression coincides with *esco2* expression, specifically in the proliferative blastemal compartment of the regenerating fin. Second, morpholino-mediated Smc3 knockdown revealed that Smc3-dependent phenotypes i.e. reduced regenerate length and segment length and decreased cell proliferation, recapitulate the *esco2/cx43*-dependent phenotypes. Third, I see a reduction in the *cx43* expression levels in Smc3 knockdown fins. Finally, *cx43* overexpression rescues Smc3-dependent phenotypes to a similar degree as Esco2-dependent phenotypes. In combination with my previous findings (Banerji et al., 2016), these results provide strong evidence that Esco2, Smc3, and Cx43 function in a common pathway and that RBS is a transcriptional malady similar to CdLS.

A popular model is that Esco2 deficiency results in mitotic failure and progenitor cell death through apoptosis. A second revelation is that, a subset of RBS-type phenotypes may instead arise directly from defects in cohesin (Smc3) binding to the promoter of clinically relevant development genes. As proof of concept, the CHIP experiments demonstrate that Smc3 physically binds to the *cx43* promoter and is required, along with Esco2, for efficient *cx43* expression. Cx43 represents a valuable and informative target given that mutation in human *CX43* results in ODDD, and that CdLS models similarly report aberrant expression of *CX43* (Monnich et al., 2011; Kawauchi et al., 2009). These results, combined with the established role for Esco2 in Smc3-

acetylation, provide compelling support for a model in which Esco2 and Smc3 act on the promoters of skeletal genes (i.e. *cx43*) to regulate transcription and thereby mediate proper skeletal development and morphogenesis (Figure 3.8).

Extensive research has been carried out to understand the structure of the cohesin complex and auxiliary factors, and their role(s) in mediating various DNA tethering events, with the intention of elucidating molecular mechanisms underlying cohesinopathies. Surprisingly, while both CdLS and RBS are grouped under a similar disease category, the etiologies of these sister maladies are considered different. Transcriptional deregulation is considered to be the primary mechanism underlying CdLS (Krantz et al., 2004; Tonkin et al., 2004; Gillis et al., 2004; Musio et al., 2006; Deardorff et al., 2007; Deardorff et al., 2012a, Deardorff et al., 2012b; Zhang et al., 2009). For example, defects in *cis*-DNA tethering events result in severe to mild phenotypes observed in CdLS. Cohesin subunits (SMC1A and SMC3) and NIPBL interact with Mediator complexes along with RNA polymerase II that bring long-distance enhancers to close proximity of the promoter of transcriptionally active genes via a *cis*-mediated DNA looping event (Kagey et al., 2010). The molecular mechanism underlying RBS is thought to occur through *trans*-tethering mitotic defects. It is true that mitotic failure and modest levels of apoptotic cells are often accompanied in mouse and zebrafish embryo studies of RBS. The current findings do not rule out the possibility that these can promote developmental defects (Monnich et al., 2011; Horsfield et al., 2012; Mehta et al., 2013; Whelan et al., 2012). However, the findings that RBS-type phenotypes can occur in the absence of apoptosis greatly diminishes these models. Instead, the data suggests a unified mechanism for both RBS and CdLS through transcriptional deregulation.

Why do RBS cells often exhibit cohesion defects (Vega et al., 2005; Schule et al., 2005)? Why do CdLS cells appear devoid of elevated levels of mitotic failure and apoptosis? I suggest contributions of gene dosage. For instance, an elegant study performed in yeast revealed differential dosage effects on a subset of cohesin related functions (Heidinger-Pauli et al., 2010). In humans, CdLS arises due to heterozygous dominant mutations in cohesion pathway genes. Thus, one functional copy of the gene may be sufficient to support cohesion but may not be sufficient to prevent changes in gene transcription. In contrast, RBS arises due to homozygous recessive mutations. Therefore, both copies of the *ESCO2* gene are defective, which blocks all cohesion pathway function such that mitotic defects appear more prevalent. My studies demonstrating that *Esco2* and *Smc3* function together to regulate *cx43* expression provide compelling evidence for a more unified model linking the underlying mechanisms of CdLS and RBS cohesinopathies.

### 3.6 Figures

**Figure 3.1: Expression of *smc3* in whole mount and cryosectioned regenerating fins.** (A) Expression of *smc3* by whole mount in situ hybridization at various time points (1, 3, 5, 8 and 14 days post amputation; dpa) (n=6 per timepoint). A solid line except in 8 dpa and 14 dpa regenerating fin indicates the amputation plane, unless it is out of the field of view. (B) In situ hybridization on 3 dpa longitudinal cryosectioned fin showing the tissue-specific localization of *smc3* mRNA. The expression is observed in most compartments of the regenerating fin, being localized strongly at the blastemal compartment (b) with moderate expression in epidermis (e), mesenchyme (m) and skeletal precursor cells (\*). The no probe control (3 dpa cryosectioned fin, right panel) shows no expression of *smc3*. Three independent trials were performed with different fin sections from 3 different fins. Scale bar is 50  $\mu$ m (shown in 3 dpa panel) for all panels.

**Figure 3.2: Validating the efficiency of *smc3* morpholinos.** (A) Schematic representation of the zebrafish *smc3* pre-mRNA with exons (e) represented with grey boxes and the regions between the exons are the introns (i). The position of MO1 (ATG blocker) at the start codon of the *smc3* gene is indicated by a blue bar (indicated on e1 with a vertical line). MO2 is positioned at the first exon and intron junction of the splice donor site (e1i1). The positions of the control primer pairs (C1-C2) are indicated with blue arrows whereas the position of the target primer pairs (P1-P2) is indicated with red arrows. (B) Western blots confirming Smc3 protein reduction (60%) in MO1 injected AB9 cell lysate (lane 2) compared to the Std-MO injected lysate (lane 1). Tubulin was used as a loading control. Similar findings were observed in each of three trials (n=10 fins per trial). (C) Results of RT-PCR analysis using C1-C2 and P1-P2 primer pairs for verifying the efficiency of MO2. The templates for both these primer pairs are numbered from 1 to 4 as follows: (1) genomic DNA extracted from regenerating fins, (2) cDNA from fins injected with Std-MO, (3) cDNA from fins injected with MO2 and (4) no template control (NTC). I used 3 fins to generate genomic DNA and 10 fins to generate cDNA. The C1-C2 primer pair amplified an expected 210 bp product. In contrast, the P1-P2 pair amplified a 729 bp product in lane 3 (marked with \*) due to the inclusion of intron1 (as predicted for MO2 injected sample) compared to lane 2 which did not amplify any product (as expected for Std-MO injected sample). (D) Schematic outline of knockdown experiments. Fins are amputated (50% level) and permitted to regenerate for 3 days. At 3 dpa, either *smc3* MOs (MO1 and MO2) or Std-MO (Standard control morpholino) was microinjected to one half of the regenerating fin keeping other half uninjected. This was immediately followed by electroporation on both injected and uninjected sides of the fin. The next day i.e. 1 day post electroporation (dpe) or 4 dpa, the injected part of the fins were evaluated for MO uptake using a fluorescence microscope.

Only those fish that showed a strong signal of the fluorescein –tagged MO were used for further experiments. For experiments such as in situ hybridization (ISH), histone-3-phosphate (H3P) and RNA extraction for RT-PCR, the fins were harvested at 1 dpe or 4 dpa. Note that for RNA extraction, all fin rays across the fin were injected with MO and electroporated before harvesting. For regenerate length and segment length measurement and analysis, fins were allowed to regenerate for longer period and were calcein stained at 4 dpe or 7 dpa. For each experiment n=8 per trial and at least 3 independent trials were performed.

**Figure 3.3: Morpholino mediated *Smc3* knockdown results in regenerate length, segment length and cell proliferation reduction.** (A) Representative images of uninjected (UN), *smc3* MO injected (MO1) and Std-MO injected fins. Total regenerate length was calculated by measuring the distance between the amputation plane (indicated by a solid black line) to the distal end of the 3<sup>rd</sup> fin ray (purple arrows indicates the length measured). (B) Graph shows the significant reduction (indicated by \*) of regenerate length in *Smc3* knockdown fins (for both MO1 and MO2) compared to the Std-MO injected fins using the percent similarity method. (C) Representative images of calcein stained fins of uninjected (UN), *smc3* MO injected (MO1) and Std-MO injected fins. Segment length was calculated by measuring the distance between first two joints in the 3<sup>rd</sup> fin ray (purple arrows indicates the length measured). (D) Graph shows that significant reduction (indicated by \*) of segment length in *Smc3* knockdown (for both MO1 and MO2) compared to Std-MO injected fins using the percent similarity method. (E) Representative images of H3P-positive cells in uninjected (UN), *smc3* MO injected (MO1) and Std-MO injected fins. Measurements were taken from the distal most 250 $\mu$ m of the 3<sup>rd</sup> ray. White bracket marks the defined area and n represents the number of H3P-positive cells in that area. (F) Graph shows the significant reduction (indicated by \*) in the number of H3P-positive cells in *Smc3* knockdown (for both MO1 and MO2) compared to Std-MO injected fins using the percent similarity method. For each experiment n=8 fins per trial and 3 independent trials were performed. For statistical significance, two tailed unpaired student's *t*-test was used where  $P < 0.05$ . Mean  $\pm$  s.e.m. is represented by error bars. Scale bar is 50  $\mu$ m for all panels.

**Figure 3.4: *smc3* regulates the expression of *cx43* in regenerating fins.** (A) Representative image of a fin with Smc3 knockdown side (*smc3*-MO) showing decreased *cx43* staining compared to the uninjected side (UN). Higher magnification of the Smc3 knockdown side of the same fin shows reduced levels of *cx43* expression compared to the uninjected side (UN), which shows normal *cx43* levels. (B) Representative image of Std-MO injected fin revealing similar *cx43* levels in both injected and uninjected side (UN). Higher magnification of the same fin shows normal and similar levels of *cx43* expression in both injected and uninjected sides (UN). For this experiment n=6 fins per trial and 3 independent trials were performed. A solid line indicates the amputation plane and scale bar is 100  $\mu$ m and 50  $\mu$ m.

**Figure 3.5: Over expression of *cx43* rescues *smc3*-dependent skeletal phenotypes.**

(A) Experimental timeline providing details of the fin amputation, MO injection/electroporation, heat shock and data analysis process. Fin amputation (50% level) was performed on transgenic *hsp70:miR-133sp<sup>pa48</sup>* fish (Tg+) and their siblings (Tg-). At 3 dpa, *smc3* MO was injected in one half of the fin keeping the other half uninjected. This step was immediately followed by electroporating both sides of the fin. After a period of 4 hours, the heat shock process began. At this point there were total 3 groups of fish: (1) Tg+HS+ is the transgenic-positive fish that were heat shocked at 37°C for 1 hour, (2) Tg+HS- is the transgenic-positive fish but were not heat shocked and (3) Tg-HS+ were the siblings (transgenic-negative) that were similarly heat shocked as Tg+HS+. At 4 dpa or 1 dpe the Tg+HS+ fins were screened for positive GFP expression, which indicated transgene induction. The control groups (Tg+HS- and Tg-HS+) were GFP-negative indicating absence of transgene induction. For regenerate length and segment length measurement and data analysis, fins were calcein stained at 7 dpa or 4 dpe. (B) The graph reveals significant (indicated by \*) rescue of *smc3*-dependent regenerate and segment length defects in Tg+HS- *Smc3* knockdown fins compared to the control groups (Tg-HS+ and Tg+HS-). For each experiment n=8 fins per trial and 3 independent trials were performed. For statistical significance, two tailed unpaired student's *t*-test was used where  $P < 0.05$ . Mean  $\pm$  s.e.m. is represented by error bars. Scale bar is 50  $\mu$ m for all panels.

**Figure 3.6: AB9 cells as a system to evaluate cohesin-binding at the *cx43* promoter.** (A) Expression of Esco2 and Smc3 are detected in AB9 cells by immunofluorescence. The anti-Esco2 antibody and anti-Smc3 antibody stains the nuclei of the cells (DAPI, blue), indicated with arrows. For each protein, 3 independent trials were performed. Scale bar is 10  $\mu$ m (B) Western blot analysis detects the Esco2 in Std-MO electroporated control cell lysates (Lane1: Control) at a predicted size of 68 kDa. A reduction in Esco2 protein levels in MO1-electroporated Esco2 knockdown cell lysate (lane 2: Esco2 KD) was observed when compared to the control sample (lane 1: Control). The results with anti-Cx43 antibody reveals reduced Cx43 protein levels (detected at 43 kDa as predicted) in Esco2 KD compared to control. Western blot analysis detects Smc3 in Std-MO electroporated control cell lysates (lane1: Control) at a predicted size of 142 kDa. A reduction in Smc3 protein levels in MO1-electroporated Smc3 knockdown cell lysate (lane 2: Smc3 KD) was observed when compared to the control sample (lane 1: Control). The results with anti-Cx43 antibody reveals reduced Cx43 protein levels (detected at 43 kDa as predicted) in Smc3 KD compared to control. Tubulin detected at 50 kDa was used as the loading control for both blots. Image J software was used for analysis of relative band intensity from data of 3 independent trials.

**Figure 3.7: Smc3 binds at a specific location of the *cx43* promoter** (A) Schematic representation of the zebrafish *cx43* promoter. It is approximately 6.7 kb in length, adjacent to an additional connexin gene (*cx32.2*). The horizontal bars indicate the binding regions of Smc3 inferred from qualitative PCR results. The positions of the seven qRT-PCR primer pairs (p1-p6) are indicated on the promoter region. The two primer pairs (p1 and p7) are the negative controls, since they lie at a region not predicted from previous PCR results. (B) The graph represents the fold enrichment of Smc3 binding (normalized to IgG) at different regions of the *cx43* promoter. Significant enrichment was observed at p2 location of the promoter suggesting positive binding of Smc3 at the p2 region. Statistical significance was determined by one-way ANOVA test ( $P < 0.001$ ) and indicated with \*. The mean  $\pm$  s.e.m. is represented by error bars for 3 independent trials.

**Figure 3.8: Esco2-dependent *cis*-DNA looping model underlying the etiology of RBS.** (A) Schematic representation of the cohesin ring complex. It is composed of two structural maintenance of chromosome (SMC) subunits (SMC1A and SMC3) and three non-SMC subunits (RAD21, SA1, 2 and PDS5). The cohesin auxiliary factor, NIPBL-MAU2 heterodimer complex helps in cohesin ring opening/closing reactions that loads cohesins onto DNA. Another auxiliary factor, *ESCO2* is a member of the *ESCO* family of N-acetyltransferases that acetylates the SMC3 cohesin subunit. (B) A model depicting the Esco2-dependent *cis*-DNA tethering mechanism underlying RBS in which the acetyltransferase Esco2 activates its target, Smc3 (denoted by Ac) that binds the *cx43* promoter, thus activating *cx43* transcription. This process is believed to occur through a *cis*-DNA looping mechanism that connects the enhancer (E) and promoter (P) of the *cx43* gene.

## **CHAPTER 4**

### **Conclusions and Future Directions**

## 4.1 Conclusions

It has been a long-standing question in the cohesinopathy field as to what is the underlying molecular mechanism of RBS/CdLS phenotypes, in part due to the diverse roles of cohesin and its auxiliary factors in various *cis* and *trans*-DNA tethering events such as cell division, chromatin organization and transcriptional processes (Ball et al., 2014; Barbero, 2014; Gerton, 2012; Horsfield et al., 2012; Mehta et al., 2013; Skibbens., 2013; Dorsett, 2016; Cucco and Musio, 2015; Zakari et al., 2015; Bose et al., 2012; Liu and Krantz, 2008; Rudra and Skibbens, 2013; Kawauch et al., 2016; Dorsett D, Merkschlager et al., 2013; Dorsett and Krantz et al., 2009; Banerji et al, 2016; Banerji et al., 2017). The past few years have witnessed important advances made in this field, however, crucial questions regarding the etiology of RBS in particular still remained unanswered. My research exploits the zebrafish regenerating caudal fin to uncover a transcriptional basis for RBS. My findings provide strong evidence that ESCO2 plays a transcriptional role and suggests that the skeletal phenotypes of RBS arise through *cis*-DNA tethering defects resulting in transcriptional deregulation of developmental programs (Banerji et al., 2016; Banerji et al, 2017 submitted).

In Chapter 2, I provide details of my findings that suggest that Esco2 knockdown results in transcriptional deregulation, independent of apoptosis, thus challenging the popular mitotic model of RBS. Using ISH and qRT-PCR techniques I show that Esco2 regulates the expression of clinically relevant *Cx43* gene, linked to a similar skeletal disorder, ODDD. By using a transgenic Cx43 overexpression line, I demonstrate rescue of Esco2-dependent skeletal phenotypes. These results provide strong evidence that link Esco2 with Cx43 during bone growth and skeletal patterning (Banerji et al., 2016). These

findings open up crucial questions regarding the mechanism underlying the Esco2-Cx43 skeletal pathway. One such question I became interested in was if Esco2 functions in a cohesin-dependent manner in regulating *cx43* expression? In Chapter 3, I extend my previous findings by testing the role of the cohesin subunit, Smc3 (a known target of Esco2) in regulating the expression of *cx43*. I show that MO-mediated knockdown of Smc3 perturbs bone and tissue regeneration. The results are similar to those previously reported for Esco2 knockdown that includes defects in bone segment growth, tissue regeneration and *cx43* expression (discussed in Chapter 2). Additionally, I provide evidence of rescue of Smc3-dependent bone and tissue regeneration defects using the transgenic *cx43* overexpression line. These findings provide evidence that Smc3 directly contributes to RBS-type phenotypes in the regenerating fin model. Moreover, ChIP assays using zebrafish AB9 cells revealed that Smc3 binds to a discrete region of the *cx43* promoter, suggesting that Esco2 exerts transcriptional regulation of *cx43* through modification of Smc3 bound to the *cx43* promoter (Banerji et al., 2017, in revision, *Biology Open*). Combined findings from Chapter 2 and 3, combined with the established role for Esco2 in Smc3-acetylation, I provide compelling support for a model where Esco2 and Smc3 act on the promoters of skeletal genes (i.e. *cx43*) to regulate transcription and thereby mediate phenotypes of RBS (Figure 3.8).

Overall, the work compiled in this dissertation highlights the following important revelations regarding the etiology of RBS. First, Esco2 knockdown in regenerating fin is established as a powerful system for elucidating the molecular basis of RBS. Second, a novel role of *esco2* in regulating the transcription of a clinically important gene, *cx43* is uncovered. Third, I show that cohesin subunit, Smc3 functions in a similar manner as

Esco2 in regulating the expression of *cx43* gene. Fourth, I provide mechanistic insights into how Esco2 regulates *cx43* expression i.e. Smc3 binds to a discrete region of the *cx43* promoter. These findings suggest a unified transcriptional mechanism that underlies both RBS and CdLS.

### **Proposed unified model of Cohesinopathy diseases**

Considering the findings from my research work, along with evidence from other groups, I challenge the notion that CdLS and RBS represent separate syndromes (Banerji et al., 2016; Choi et al., 2010; Kim et al., 2008; Morita et al., 2012; Kaur et al., 2005; Ghiselli et al., 2006; Fazio et al., 2016; Pistocchi et al., 2013; Schuster et al., 2015; Leem et al., 2011; Xu et al., 2016). My work provides tangible evidence for a unified mechanism underlying RBS and CdLS (discussed in the review article, Banerji et al., 2017, in revision). It is important to take into consideration findings from various groups and reinterpret the underlying mechanisms of RBS/CdLS. Currently, there is enough evidence that mutations in *esco2* not only impact apoptosis but also transcriptional regulation. Furthermore, along with transcriptional deregulation there is evidence that mutations in genes associated with CdLS also cause apoptosis through mitotic failure (Kaur et al., 2005; Ghiselli, 2006; Fazio et al., 2016; Schuster et al., 2015; Pistocchi et al., 2013; Leem et al., 2011, Choi et al., 2010, Banerji et al., 2016, Xu et al., 2016; Cucco and Musio, 2016). But why do cells from RBS and CdLS exhibit distinct morphology? Why are cohesion defects a prominent feature of RBS and not apparent in CdLS?

I speculate that the lack of cohesion defects in CdLS is due to the heterozygosity involved in the disease. CdLS arise due to dominant mutations in genes coding for structural components of the cohesion ring (Krantz et al., 2004; Tonkin et al., 2004; Musio et al., 2006; Deardorff et al., 2007; Deardorff et al., 2012a; Deardorff et al., 2012b; Yuan et al., 2015; Liu and Krantz, 2009). In contrast, RBS is caused by recessive mutations in the gene coding for an enzymatic activity that regulates ring closure (Vega et al., 2005; Schule et al., 2005; Gordillo et al., 2008). Thus dosage of the cohesion pathway genes may play a vital role in this purpose. For instance, RBS cells and model systems exhibit significant loss of cohesion function resulting from *trans*-DNA tethering defects (Monnich et al., 2011; Morita et al., 2012; Percival et al., 2015; Whelan et al., 2012; Van der Leijj et al., 2009). These mitotic failures, and the subsequent induction of apoptosis, potentially disguise underlying *cis*-DNA tethering defects. My PhD. thesis work suggests that a moderate loss of Esco2 function results primarily in *cis*-DNA tethering defects. Autosomal recessive transmission for RBS is consistent with requiring a greater decrease in ESCO2 to achieve transcriptional defects. At this reduced level of ESCO2 function, chromosome segregation defects also are prominent. On the other hand, autosomal dominant transmission requires only a modest loss of cohesion pathway activity, leading to defects in transcription. At this level of function, mitotic defects are not prominent. Therefore, I can propose that transcriptional deregulation is the predominant mechanism through which both RBS and CdLS arise, although the contributing role for mitotic failure and apoptosis cannot be ruled out (Figure 4.1). Further studies are required for support for the unified model of cohesinopathies. Below,

I summarize some of the future directions that would provide additional evidence for the transcriptional model of RBS.

## **4.2 Future Direction**

### **(1) To determine if the Smc3 association with the *cx43* promoter is dependent on Esco2 acetylation**

In Chapter 3, I provide evidence of Smc3 binding to the *cx43* promoter region and provide support of a cohesin-mediated Esco2-dependent model of RBS (Figure 3.8). In this model, it is proposed that acetyltransferase activity of Esco2 is required for the activation its target, Smc3 that binds the *cx43* promoter, thus regulating *cx43* transcription. This model is based on the consideration that Esco2 functions as its established role of an acetyltransferase (Bellows et al., 2003; Skibbens et al., 1999; Toth et al., 1999; Ivanov et al., 2002; Zhang et al., 2008; Unal et al., 2008; Ben-Shahar et al., 2008; Hou and Zou, 2005). Thus it will be interesting to test the established role of Esco2 in regulating *cx43* expression. To functionally link Smc3 binding and gene regulation with Esco2 activity, it is important to test if Smc3 binds to the *cx43* promoter in a Esco2-dependent fashion. This could be achieved by performing Smc3-ChIP at the *cx43* promoter on Esco2 knockdown AB9 cells. If significant Smc3 binding is not observed at the p2 region of the *cx43* promoter in Esco2 knockdown cell lysates, then that infers the Esco2 dependency in the proposed cohesin-mediated transcriptional model of RBS, supporting the hypothesis. The results for this experiment are extremely important to further strengthen the proposed model and provide evidence that Esco2 functions as an acetyltransferase and thus activating cohesins.

## **(2) Promoter analysis of *cx43* to determine the functional sequence required for Smc3 binding for regulating *cx43* expression**

Future studies should be aimed to quantify and detect measurable changes in transcription from the putative *cx43* promoter. For achieving this goal reporter constructs for *cx43* can be generated. The zebrafish *cx43* promoter is approximately 6.7 kb in length, adjacent to an additional connexin gene (*cx32.2*) that resides upstream of the *cx43* coding sequence (Chatterjee et al., 2005). AB9 cells can be transfected with *cx43*-luciferase reporters followed by detection of transcription. This experiment is important to answer two important questions. First, with this set up the functional impact of Esco2 dependency can be tested. For example, the luciferase assay (Solberg and Krauss, 2013) can be performed on Esco2 knockdown AB9 cells followed by luciferase quantification that will determine the functional requirement of Esco2 on *cx43* transcription. Second, in order to determine the functional promoter sequence requirement, *cx43* reporter constructs with point mutations and deletions in the *cx43* promoter can be generated followed by measurement of transcription. These experiments would provide additional evidence in support of the RBS transcriptional model (Figure 3.8).

## **(3) To demonstrate chromosome looping as a mechanism of transcriptional regulation in RBS**

Genome-wide studies show strong evidence of direct association of cohesin subunits and its auxiliary factors with developmental genes. One of the possible mechanisms underlying the transcriptional regulation of cohesin is via long distance DNA loops. The DNA loop formation during transcription is not new concept, as there are historical

evidence of such phenomenon in bacteria and bacteriophage systems (Ptashne, 1986; Hoover et al., 1990; Luijsterburg et al., 2008; Saiz and Vilar, 2006; Kagey et al., 2010). There are several evidences from various groups that show cohesin facilitates such looping mechanism (Hadjur et al., 2009, Mishiro et al., 2009; Nativio et al., 2009; Hou et al., 2010). Interestingly, in mouse embryonic stem cells cohesin binding initiates enhancer-promoter interaction via DNA loops in transcriptionally active genes (Kagey et al., 2010). This study provides *in vivo* evidence of physical interaction and co-occupancy of the cohesin, mediator and NIBPL at the enhancer and core promoter regions of particularly active genes (Figure 1.2). Keeping this mechanism as a common notion during transcriptional regulation, I propose a cohesion-mediated Esco2 dependent model of RBS (Figure 3.8), where activated Smc3 binds to the *cx43* promoter region that facilitates conformational changes bringing the enhancer- *cx43* promoter in close proximity. In Chapter 3, I provide evidence of Smc3 association with the *cx43* promoter region, but it is important to test if the mechanism is via chromatin looping and also the involvement of enhancers in *cx43* regulation. The spatial organization of chromatin can be tested by performing Chromosome conformation capture (3C) technique (Kagey et al., 2010).

#### **(4) To determine if Esco2 regulates *cx43* transcription via association of transcription factors**

I provide support of a cohesin-dependent mechanism of *cx43* regulation, which is one of the many ways that *cx43* could be regulated by Esco2 (Chapter 3). There lies a possibility that the link between Esco2 and Cx43 is cohesin-independent (Figure 4.2).

Transcription factors can bind to Esco2 in regulating *cx43* expression. One potential candidate is *notch*, since a similar role of Esco2 in regulating *notch* transcription has been previously reported (Leem et al., 2011). Notch signaling is evolutionary conserved in all vertebrates and is crucial for regulating various developmental programs. The transcription factor *notch* associates with Esco2 and is sequestered away from the promoter binding sites during the differentiation of neuronal cells. Another study reported reduction in *notch1a* expression in Esco2 depleted medaka mutants (*esco2<sup>R80S</sup>*) providing additional evidence of Esco2 and Notch association (Morita et al., 2012).

Another potential transcription factor that may also play an important role is CTCF. There are many evidence that link cohesin and CTCF and suggest their role in gene expression (Wendt and Peters, 2009; Wendt et al., 2008; Hadjur et al., 2009; Hou et al., 2010; Kagey et al., 2010; Ball et al., 2014; Parelho et al., 2008; Rubio et al., 2008; Degner et al., 2011; Nativio et al., 2011; Majumder and Boss, 2011; Guo et al., 2012). In a 2008 study, 9000 cohesin sites were mapped in the entire non-repetitive part of the human genome, which showed 89% of these sites identical with CTCF sites (Wendt et al. 2008). It will be interesting to see if these factors are dependent on Esco2 and if yes, then how is *cx43* expression affected. This is important to understand the alternative mechanisms that may link Esco2 and Cx43 during skeletal growth and patterning. If this model is true, it will provide evidence that Esco2-binding factors may regulate *cx43* expression, which is separate from its well-established acetyltransferase role. The schematic of the proposed model is depicted in Figure 4.2.

Additionally there are few transcription factors that are reported to associate with *cx43* but their dependency on Esco2 is yet to be tested. The list of genes that can be

included to test the model (Figure 4.2) are *Nkx2.5*, *Runx2*, *Tbx2* and *Tbx3*, *SOX4*, and *SOX2*,  *$\beta$ -catenin*, and *Msx1* (Chatterjee et al., 2005; Boogerd et al., 2011; Xia et al., 2010; Boogerd et al., 2008; Chen et al., 1995; Chatterjee et al., 2001). These factors could either induce or repress *cx43* expression but their link with *Esco2* needs to be tested.

**(5) To determine if *Esco2* regulate *cx43* transcription by the association of chromatin-remodeling complexes**

It is now widely accepted that eukaryotic gene expression is regulated not only by basal transcriptional machinery but also by chromatin structural changes. Thus it is possible that *Esco2* recruits chromatin-remodeling complexes to *cx43* promoter for regulating its transcription. There are evidence that suggest association of *Esco2* with the CoREST complex and also with other chromatin modifying enzymes (Kim et al., 2008). Other evidence show chromatin- remodeling complexes such as methyltransferases (SETDB1, G9a and *suv39h1*) and demethylases (LSD1) bind to *Esco2* independent of acetyltransferase activity (Choi et al., 2010; Skibbens et al., 2013). Involvement of such factors will provide additional mechanisms through which *Esco2*-binding factors may regulate *cx43* expression which is separate from it's well established acetyltransferase role. The schematic of the proposed model is depicted in Figure 4.2. Similarly, it will be interesting to test the *Esco2* dependency on this model and to determine how *cx43* expression is affected.

**(6) To determine novel binding partners of Esco2 in regulating *cx43* expression**

Currently, very few known partners of Esco2 have been identified. In order to understand the alternative mechanisms underlying Esco2-Cx43 regulation it will be valuable to adapt *a priori* approach for identifying novel binding partners of Esco2. Since my findings show that Esco2 knockdown results in reduction of *cx43* expression, it is possible that there are novel partners that participate in direct binding of repressors away from the *cx43* promoter. To address this strategy, mass spectrometric analysis can be performed to identify Esco2 associated factors. This should be followed by testing for candidate factor binding to *cx43* promoter in the presence and absence of Esco2. Generation of a candidate list will be extremely helpful for testing the physical link between the candidates and Esco2. This strategy of producing a candidate list of Esco2-dependent binding factors will open up new ways to identify possible mechanisms underlying Roberts Syndrome.

### 4.3 Figures

**Figure 4.1: Mechanisms of cohesinopathies.** Transcriptional deregulation caused by defects in *cis*-DNA tethering events is the predominant mechanism through which both RBS and CdLS arise. The extent to which mitotic failure and apoptosis caused by defects in *trans*-DNA tethering events contribute to cohesinopathies requires further inquiry.

**Rajeswari Banerji**  
Curriculum Vitae

Lehigh University  
Department of Biological Sciences  
111 Research Drive, B-217  
Bethlehem, PA 18015

**Education:**

- 2011 – May, 2017     **Ph.D. Candidate, Cell and Molecular Biology**  
Lehigh University, Bethlehem, PA  
Advisor: Mary Kathryn Iovine, Ph.D.  
Co-Advisor: Robert V. Skibbens  
Title: The regenerating fin as a model to examine the skeletal defects of Roberts Syndrome  
**Current GPA: 4.0**
- 2005- 2007     **M.Sc., Biotechnology, Amity Institute of Biotechnology.**  
Amity University, Noida, India, CGPA – 8.27
- 2002- 2005     **B.Sc. (Hons.), Biotechnology, Amity Institute of Biotechnology.**  
CCS University, Meerut, India  
First division, 72%

**Experience:**

- Lehigh University, Bethlehem, PA     August 2011 – Present  
Department of Biological Sciences  
Graduate Research/Teaching Assistant
- The Centre for Genomic Application, New Delhi     February 2008 – September 2009  
Research Biologist, Microarray Department
- International Medical Research Organization, Kolkata     May 2005- June 2005  
Clinical Research Associate

**Training:**

*Master's degree:*

1. Undertook a 2 months training during M.Sc. (Sem-II) at Department of Biological Chemistry, Indian Association for Cultivation of Science, Kolkata, under a project

entitled ‘*Isolation of Fungi having Chitosanase Activity followed by Partial Purification of Chitosanase*’.

2. All India Institute of Medicinal Sciences (AIIMS), Ocular Biochemistry, Project title: ‘*Study of Various Biochemical Parameters in Uveitis*’.
3. The Centre for Genomic Applications (TCGA), Delhi. Project title: ‘*Analysis of loci 5, 6, 10 and 15 of IS900 element in the Indian ‘Bison type’ MAP isolate ‘S5’*’. Techniques applied in the project were Polymerase Chain Reaction, DNA sequencing and Multiple Alignment by Clustal W.

*Undergraduate degree:*

4. Amity Institute of Biotechnology. Project title: ‘*Isolation and Assessment of Bacterial Activity in Yamuna Water*’. The aim was to show the water balance in New Delhi and the harmful effects it could cause.
5. Training during M.Sc. (Semester-II) at Department of Biological Chemistry, Indian Association for Cultivation of Science, Kolkata.

#### **Fellowships:**

1. Lehigh University, College of Arts & Sciences Summer Research Fellowship, 2013
2. Lehigh University, Nemes Fellowship, Fall 2015

#### **Manuscripts:**

1. **Banerji R**, Eble D. M., Iovine M. K. and Skibbens R. V. (2016). Esco2 regulates *cx43* expression during skeletal regeneration in the zebrafish fin. *Developmental Dynamics*, 245(1), 7-21. doi: 10.1002/dvdy.24354
