## ABSTRACT

Insufficient data exists on the effects of prompt fast neutron activation on metals found commonly in nuclear devices and the urban environment. Different metals such as Ti, Au, Fe, and Cu were activated using the Flattop Criticality Benchmark at the Device Assembly Facility on the Nevada Test Site using a known neutron spectra and flux to determine a baseline cross section value. Cross section information gathered from these neutron activation measurements could provide information that helps government and law enforcement agencies to correctly trace the origin of a nuclear device's fuel or component features.

Based on activation products produced in the Flattop benchmark irradiations, chemical separation methods were developed to isolate higher specific activity samples for doping simulated urban melt glass debris. Extraction chromatography batch contact studies using resins from Eichrom Technologies were performed to determine the retention of stable scandium and titanium. Column studies adapted from these contact studies were optimized using higher mass loading for later use to purify  $^{46}\text{Sc}$ ,  $^{47}\text{Sc}$ , and  $^{48}\text{Sc}$  produced from natural titanium through the n-p nuclear reaction.

This method shown above could also be applied to the field of nuclear medicine for use in extracting  $^{44}\text{Sc}$  (a positron emitter) from  $^{44}\text{Ti}$ . Positron emitting radionuclides such as  $^{44}\text{Sc}$ , or more commonly  $^{13}\text{C}$ ,  $^{14}\text{N}$ , and  $^{18}\text{F}$  can be utilized in Positron Emission Tomography (PET), which is a form of nuclear diagnostic medicine used to model metabolic processes. All of these isotopes have half-lives of a few minutes to a few hours, which requires localized medical cyclotrons and chemistry laboratories for production followed by separation.

In recent years, interest has been shown in using longer-lived radioisotopes such as  $^{52}\text{Mn}$  for positron emission tomography, which has a significantly longer half-life of 5.591 days and similar positron decay energy. The isotope  $^{52}\text{Mn}$  could easily be produced at a cyclotron, chemically separated, and shipped further distances allowing for a wider use of PET while minimizing the need to purchase cyclotrons and chemistry laboratories. In this research, chemical separation methods solvent extraction and extraction chromatography were employed to separate stable Mn from Cr using trioctylamine (TOA) ligand. Once developed, this method will be used to separation medically produced quantities of  $^{52}\text{Mn}$  from  $^{52}\text{Cr}$ .

## TABLE OF CONTENTS

ABSTRACT.....	iii
LIST OF TABLES.....	x
LIST OF FIGURES.....	xii
CHAPTER 1: INTRODUCTION.....	1
1.1 Motivation for Research.....	1
1.2 Research Goals.....	3
1.3 Dissertation Overview.....	4
1.4 Nuclear Forensics.....	5
1.4.1 Pre and Post Detonation Analysis.....	6
1.4.2 Neutron Activation.....	9
1.4.3 Flattop Critical Assembly Benchmark.....	10
1.4.4 Application to Research.....	13
1.5 Nuclear Medicine.....	15
1.5.1 Application to Research.....	18
CHAPTER 2: CHEMICAL SEPARATIONS.....	20
2.1 Solvent Extraction.....	20
2.2 Extraction Chromatography.....	23
2.3 Application of Separation Methods.....	26
2.3.1 Extraction of Scandium from Titanium.....	26
2.3.2 Extraction of Manganese from Chromium.....	30
CHAPTER 3: METHODOLOGY.....	33
3.1 Materials.....	33
3.2 Cross Section Determination using Flattop Criticality Benchmark.....	34
3.2.1 Experimental Procedure.....	34
3.2.2 Flattop Data Analysis.....	34
3.2.2.1 Gamma Spectra Analysis.....	34
3.2.2.2 Flux and Cross Section Determination.....	35
3.3 Solvent Extraction Research.....	37
3.3.1 Solvent Extraction Study.....	37
3.3.1.1 Experimental Procedure.....	37
3.3.1.2 Data Analysis.....	37
3.3.2 Kinetic Study.....	38

3.3.2.1 Experimental Procedure.....	38
3.3.2.2 Data Analysis .....	38
3.3.3 Third Phase Formation Study .....	38
3.3.3.1 Experimental Procedure.....	38
3.3.3.2 Data Analysis .....	38
3.4 Batch Contact Research .....	39
3.4.1 Batch Contact Studies .....	39
3.4.1.1 Experimental Procedure.....	39
3.4.1.2 Data Analysis .....	39
3.4.2 Kinetic Batch Contact Study.....	39
3.4.2.1 Experimental Procedure.....	39
3.4.2.2 Data Analysis .....	40
3.4.3 Batch Contact Volume Correction.....	40
3.4.3.1 Experimental Procedure.....	40
3.4.3.2 Data Analysis .....	40
3.5 Column Studies.....	41
3.5.1 Gravity Column Studies.....	41
3.5.1.1 Experimental Procedure.....	41
3.5.1.2 Data Analysis .....	42
3.5.2 Vacuum Column Studies .....	42
3.5.2.1 Experimental Procedure.....	42
3.5.2.2 Data Analysis .....	43
3.6 Instrumentation .....	43
3.6.1 Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES) .....	43
3.6.1.1 Theory .....	43
3.6.1.2 Analysis Method .....	44
3.6.2 Inductively Coupled Plasma Mass Spectrometry (ICP-MS) .....	44
3.6.2.1 Theory .....	44
3.6.2.2 Analysis Method .....	45
3.6.3 High Purity Germanium (HPGe) Well Detector.....	45
3.6.3.1 Theory .....	45
3.6.3.2 Analysis Method .....	45

CHAPTER 4: DETERMINATION OF FAST NEUTRON CROSS SECTIONS USING ELEMENTS IRRADIATED ON THE FLATTOP CRITICALITY BENCHMARK .....	46
4.1 Introduction.....	46
4.2 Materials .....	46
4.3 Experimental Procedure.....	47
4.3.1 Metal Foil Measurements.....	47
4.3.2 Data Analysis.....	49
4.3.2.1 Gamma Spectra Analysis.....	50
4.3.2.2 Flux and Cross Section Determination .....	50
4.4 Results and Discussion .....	50
4.4.1 Activity at Time Zero.....	50
4.4.2 Flux Determination .....	52
4.4.3 Cross Section Determination .....	55
4.5 Conclusion .....	58
CHAPTER 5: BATCH CONTACT STUDIES OF SCANDIUM AND TITANIUM ON EXTRACTION CHROMATOGRAPHY RESINS FOR SEPARATION METHOD DEVELOPMENT .....	60
5.1 Introduction.....	60
5.2 Materials .....	60
5.3 Experimental Procedure.....	61
5.3.1 Stock Solution Preparation .....	61
5.3.2 Ln 1 Resin.....	61
5.3.2.1 Batch Contact Studies.....	61
5.3.2.2 Data Analysis.....	62
5.3.3 DGA Normal Resin.....	62
5.3.3.1 Batch Contact Studies.....	62
5.3.3.2 Data Analysis.....	63
5.3.3.3 Kinetic Batch Contact Study.....	64
5.3.3.4 Data Analysis .....	64
5.4 Results and Discussion .....	65
5.4.1 Ln 1 Resin .....	65
5.4.2 DGA Resin.....	68
5.4.2.1 Single Analyte Batch Studies.....	68

5.4.2.2 Kinetic Batch Study .....	70
5.4.2.3 Dual Analyte Batch Studies .....	72
5.4.2.4 Comparison of Scandium Retention Studies .....	75
5.4.2.5 Comparison of Titanium Retention Studies.....	82
5.5 Conclusions.....	85
CHAPTER 6: SEPARATION OF TITANIUM AND SCANDIUM USING DGA RESIN COLUMN STUDIES.....	87
6.1 Introduction.....	87
6.2 Materials .....	87
6.3 Experimental Procedure.....	88
6.3.1 Gravity Column Studies.....	88

## CHAPTER 1: INTRODUCTION

### 1.1 Motivation for Research

“The Manhattan Project, effected by the United States during World War II, forever changed the technical, social and political framework of the world.”<sup>1</sup>

Development of the nuclear industry led to the significant advancement in energy production, medical treatments, and weapon capabilities. Fission of a nucleus provided the capability to release  $10^9$  times more energy than the exothermic release from a chemical reaction of equal mass. Controlled nuclear reactions can be used to produce energy in a reactor, or used to produce radioisotopes useful to irradiation of cancerous tumors. However, the main driving force behind the advent of nuclear technology was for the development of significantly more devastating weapons compared to conventional explosives.

In the summer of 1945, two nuclear weapons, nicknamed Little Boy and Fat Man were dropped on Japan over the course of three days. Little Boy, a gun-type design fueled by  $^{235}\text{U}$  with an explosive yield of ~15 kilotons, and Fat Man, an implosion type design fueled by  $^{239}\text{Pu}$  with an explosive yield of ~21 kilotons, caused a combined 210,000 fatalities by the end of 1945.<sup>1</sup> Single explosive devices of such devastation had never been seen before hence the name “Weapons of Mass Destruction”.

After WWII, an arms race began between the United States and the Soviet Union (USSR) leading to proliferation in the number, type, and explosive yield of nuclear weapons. By 1986, the Soviet Union had an arsenal of 45,000 warheads averaging five hundred kilotons each which was enough to destroy over 60% of the United States land and water mass from the combination of the initiation detonation and the subsequent radiation fallout.<sup>1</sup> The United State of America had

comparable arsenal as well which led to the term Mutually Assured Destruction (MAD) defining the state of the world where either side could completely annihilate at least 40% of an adversary's population and 70% of its industry. Even today, after the Cold War, after significant reduction in the nuclear weapons stockpile, the United States and Russia each possess thirty four tons of weapons-grade plutonium waiting for disposal with a total potential up to 20,000 weapons if placed in the wrong hands.<sup>2</sup> In attempts to safeguard against use of these weapons, forensic methods have been developed in an attempt to deter smuggling or misuse of nuclear materials.

In addition to a new class of weapons, the field of medicine was advanced by the nuclear industry. Use of radioisotopes produced from nuclear reactors or accelerators have allowed for significant advancements in imaging, diagnostics, and treatment in the fields of oncology, cardiology, and neurology. Generally, gamma and x-ray emitters are useful for imaging tumors or tracing the biological pathways of compounds in the human body. This is performed through the addition of a tracer (radionuclide) to a biomolecule that emits electromagnetic radiation as it passes through the system. The electromagnetic radiation produced from annihilation of a beta and electron is measured using a detector and is converted images. Alpha and beta emitters are useful for treating tumors through localized emission of radiation to cancer cells. An example of this method is through the use of the  $^{131}\text{I}$  tracer which will concentrate in the thyroid gland.<sup>3-5</sup>

In either case, the production of nuclear fuels for weapons or radioisotopes used for medical applications require separation methods to isolate isotopes of interest. In the case of nuclear fuels, separations can be utilized to measure specific chemical or physical characteristics linking materials to their production sources. In this dissertation work, chemical separation methods were applied to concentrate radioisotopes to determine nuclear information useful for post detonation nuclear forensics and isolate radioisotopes to perform imaging of the human body.

## 1.2 Research Goals

In the 1<sup>st</sup> portion of the dissertation, the fast neutron reaction capture cross sections of elements found in the earth's crust, weapon device composition, and urban construction materials was determined using gamma decay measurements of activated metal foils. These activated metal samples were produced simulating the effects of  $^{235}\text{U}$  fission using the Flattop Benchmark Critical Assembly. Batch contact studies using extraction chromatography (EXC) resins from Eichrom Technologies were performed to measure the retention of stable scandium and titanium in varying concentrations of mineral acids. Additional kinetic studies were performed to insure sufficient extraction was performed. Based on the optimal separation factor, the separation conditions were applied to gravity column studies to separate Sc from Ti followed by adaption to vacuum column studies allowing a significant increase in mass loading to simulate the quantities of  $^{46-50}\text{Sc}$  produced from activated  $^{\text{nat}}\text{Ti}$  foil.

In the 2<sup>nd</sup> portion of the dissertation, solvent extraction (SX) was employed to separate stable Mn from Cr. This work is being performed for the purpose of isolating activated  $^{52}\text{Mn}$  from  $^{52}\text{Cr}$  for use in positron emission tomography (PET). Based on previous SX studies using the trioctylamine (TOA) ligand, quantification and improvements in third phase reduction, extraction kinetics, and retention studies were performed to determine optimal separation parameters. Resins based on the SX studies were produced through Triskem International SAS for characterization by batch contact studies to determine separation potential.

### **1.3 Dissertation Overview**

Chapter 1 provides a general introduction to nuclear forensics and nuclear medicine in addition to the project goals for this dissertation. Chapter 2 provides background information on the separation methods used for the project goals. Chapter 3 provides experimental procedures, data analysis, and background on instruments utilized. Chapter 4 displays the results of the neutron activation on metal foils using the Flattop Critical Benchmark Assembly followed by flux and cross section determination. Chapter 5, 6, 7, and 8 consist of experimental separation studies followed by discussion of the results. Chapter 5 shows the use of extraction chromatography resins for batch contact studies of titanium and scandium. Chapter 6 shows the gravity and vacuum column separation studies of titanium and scandium based on the work in chapter 5. Chapter 7 shows the solvent extraction studies of manganese from chromium. Chapter 8 shows the use of extraction chromatography resins based on chapter 7 to separate manganese from chromium. Chapter 9 provides a conclusion of the work followed by an appendix displaying all of the raw data for the dissertation.

## 1.4 Nuclear Forensics

In the event of a nuclear detonation, significant quantities of fissile material ( $^{233}\text{U}$ ,  $^{235}\text{U}$ , or  $^{239}\text{Pu}$ ) or fissionable material ( $^{237}\text{Np}$ ,  $^{238}\text{U}$ , or  $^{234}\text{U}$ )<sup>1</sup> in a supercritical form will fission emitting thermal energy, radioactive particles, and fission products. Characteristics of the device, in addition to the altitude of the detonation will affect the distribution of energy and the prompt versus long term radiation effects from nuclear fallout. As part of the detonation, an enormous flux of fast neutrons ( $10^{20}$  at ground zero for a device on the surface)<sup>6</sup> would be emitted varying by distance from the epicenter. The surrounding environment will be irradiated by neutrons in the form of scatter or capture reactions and gamma/X-rays which contribute significantly to the dose received near ground-zero.

The magnitude of the blast and energy of the emitted particles is determined by the isotopics of the fuel being used and the type of device being utilized. The three fissile isotopes designated special nuclear materials (SNM) refer to  $^{233}\text{U}$ ,  $^{235}\text{U}$ , and  $^{239}\text{Pu}$ . Fissile isotopes are able to fission through the capture of thermal (0.025 eV) neutrons causing the nucleus to be excited causing deformation releasing into two primary fission fragments along with neutrons and gamma radiation.

There are two general methods used in employment of supercritical masses. The one stage fission device also known as the gun type weapon involves two subcritical masses propelled by an explosive assembling a supercritical mass. One stage fission devices are usually composed of  $^{235}\text{U}$  or  $^{233}\text{U}$ . The second method, known as an implosion device involves a subcritical mass of fissile fuel surrounded by explosive propellant. Compression of a subcritical mass causes the fuel density to drastically increase while decreasing the surface area. Additionally, boosting was developed to

greatly increase the number of high energy neutrons release useful for extend the longevity and efficiency of the fission fuel process.<sup>1</sup> With the rapid compression by the explosive propellant, the pressure and temperature increase radically causing fusion to occur in the secondary component. Fusion as opposed to fission occurs through the combination of smaller atomic masses isotopes (e.g. D-D, Li-D, D-T) producing fast energy neutrons. These neutrons energies vary from 3 to 4 MeV for D-D fusion and 14 MeV for D-T.<sup>1</sup>

It is important to note that each different fuel type has different enrichment thresholds needed to be considered weapons grade material. For  $^{235}\text{U}$ , weapons grade fuel consists of greater than 90% (93.5 wt.% in the US) while  $^{239}\text{Pu}$  requires greater than 93%  $^{239}\text{Pu}$  and 7% or less  $^{240}\text{Pu}$ . Different quantities are necessary based on properties of the device such as propellant and reflectors. A bare isolated sphere of critical mass needs far greater quantities of fuel (52 kg for  $^{235}\text{U}$ ) as opposed to a fully reflected sphere (17 kg  $^{235}\text{U}$ ). However, a bare isolate sphere of about 10-15 kg of  $^{239}\text{Pu}$  (based on metallurgical phase) or  $^{233}\text{U}$  would be all that is needed for supercriticality.<sup>6</sup>

#### **1.4.1 Pre and Post Detonation Analysis**

In the field of nuclear forensic analysis (NFA), there is pre-detonation and post detonation analysis. Pre-detonation analysis involves measurements of isotopic signatures and other well characterized features of fuels, device materials, and or entire weapons which are generally traceable to unique manufacturing and enrichment processes of each nuclear state. Post detonation analysis is significantly more complicated as the process of a nuclear detonation will alter the isotopic makeup of the fuel through fission creating fission products and releasing radiation through heat and particulates that will changed the surrounding environmental. Depending where

the device is detonated will greatly affect how the components are spread out and mixed in the surrounding area. It is unlikely that a significant fraction of the total analyte inventory will be recovered for analysis.<sup>1</sup>

The ability to trace information about the initial device has to be reverse engineered based of what can be recovered. Each fuel type ( $^{233}\text{U}$ ,  $^{235}\text{U}$ , and  $^{239}\text{Pu}$ ) has different fission product yield, average neutron yield, and average neutron energy spectra which can be used to work backwards to characterize the initial device. The isobar yield of fission by thermal and fast neutron on  $^{233}\text{U}$ ,  $^{235}\text{U}$ , and  $^{239}\text{Pu}$  is shown below in figure 1.

Figure 1: Isobar yield of fission of  $^{233}\text{U}$ ,  $^{235}\text{U}$ , and  $^{239}\text{Pu}$ <sup>7</sup>

Each of the spectra differ enough that it may be feasible to trace enough information about the device employed if the distribution of products was evenly spread. However, the radioactive products will fractionate based on their relative volatility to a degree based the altitude, location, weather patterns as well as inconsistent mixing with the natural and urban environment. Previous nuclear testing performed were used to see the effects on the natural environment, but no testing has been performed on a contemporary urban center. The common urban environment consists mainly of roads, sidewalks, buildings, and automobiles which are comprised of cement, concrete, metal, and glass. In the US, a standard composition for each common form of these materials has been determined by the National Institute of Standards and Technology (NIST) which is invaluable for post detonation analysis. Fast-neutrons (1-20 MeV)<sup>8</sup> released from a detonation will interact with elemental nuclei in these materials through capture or scatter reactions. Capture reactions are of particular interest, as they will produce activation products based on the neutron flux and energy of the fuel employed in the detonation.<sup>6</sup>

Post detonation analysis includes nondestructive (NDA) and destructive analysis (DA) methods to collect information from debris such as melt glass. The NDA method generally refers to radioanalytical measurements of samples to gain insight about isotopic composition. Isotopes such as <sup>137</sup>Cs, are ideal due to their significant  $\gamma$  transition ratios and small number of unique full energy photopeaks. Other NDA tools such as microscopy are generally useful to gain morphological or structure characteristics used in sample preparation. Samples with very high versus low activity would ideally be treated differently such as would melt glass versus metal samples. In many cases, conclusive information cannot be gained through NDA such as in the case of multiple isotopes with interfering decay schemes or energies.

The DA method is essential for forensic samples such as melt glass that require changes in physical and or chemical properties to measure other forms of radiation. Alpha, beta and x-ray radiation has a significantly shorter range than gamma rays and will likely be attenuated in a solid sample. Other methods can be employed to measure isotopic and elemental abundance information through use of inductively coupled plasma mass spectrometry (ICP-MS) or optical emission spectroscopy (ICP-OES) for samples in the ppm to ppt range. These methods are generally used for lower activity samples. More information on these instruments is shown below in chapter 3.

#### **1.4.2 Neutron Activation**

The process of neutron activation is used to simulate the effects of a specific neutron spectra irradiating samples to produce radioisotopes. NDA of radioisotopes with neutrons is known as Neutron Activation Analysis (NAA) while radioisotopes produced required chemical separation to remove interfering species or require concentration to increase specific activity is known as Radiochemical Neutron Activation Analysis (RNAA).<sup>1</sup> The general equation for neutron activation is shown below as equation 1.

$$R_p = N \cdot \Phi \cdot \sigma \quad (1)^8$$

$R_p$  or the rate of isotope production is determined from the initial flux of neutrons per unit volume  $\Phi$ , the capture cross section  $\sigma$ , and the number of targets per unit volume  $N$ .<sup>8</sup> The flux and targets employed can vary based on the needs of the production experiment while the cross section

is a physical constant based on the probability of capture of a neutron at a given energy for a specific isotope. In an ideal situation, the neutron flux and average neutron energy can be determined based on measuring the abundance and isotopic ratios of activation. However, in a real world situation, activation products like fission products would be heterogeneously distributed and activation product isotopics would be used synergistically with fission product isotopics to trace origin of the material.

### **1.4.3 Flattop Critical Assembly Benchmark**

Reverse engineering device information from an urban detonation requires simulating the effects of fissioning each fuel type on a known composite material (such as the previously mentioned NIST standards). With the self-imposed moratorium on nuclear testing in 1992,<sup>1</sup> a different method would be needed to simulate this process.

Multiple benchmark critical assemblies built prior to the moratorium have been used to measure the effects of fissile species in various configurations including physical form, mass of fuel, power levels, and level of neutron reflection. Among them, the Flattop bench mark critical assembly, was specifically for the purpose of fast neutron activation to measure reactivity coefficients. Neutronic data for critical masses of  $^{233}\text{U}$ ,  $^{235}\text{U}$ , and  $^{239}\text{Pu}$  has been meticulously characterized in this instrument allowing precise cross section verification for weapons and reactor programs.<sup>9</sup> Using Flattop, common elements in urban materials were activated using a precise neutron energy spectrum meant to approximate a fast neutron flux from nuclear detonation.

A schematic structure of the Flattop critical assembly machine version used for this research is shown below in figure 2 for an aerial view and in figure 3 for a side view. Flattop is comprised a core of highly enriched uranium (HEU) enclosed in a thick natural uranium reflector.

The core consists of two screwed together sitting on a pedestal track that can be positioned using a hand crank. The reflector is split into one stationary hemisphere, and two moveable quarter spheres on tracks. One sphere is moved using either hydraulic pressure while the other uses a motor. Additionally, there are three voids that can be filled with plugs or control rods composed of natural uranium to control the neutronics of the system. Finally there is a glory hole between the two quarter spheres going into the HEU core where samples were placed for irradiation.<sup>9,10</sup> An image of the Flattop assembly is shown below in figure 4.

Figure 2: Schematic of Flattop (Aerial View)<sup>10</sup>

Figure 3: Schematic of Flattop (Side View)<sup>10</sup>

Figure 4: Flattop Benchmark Criticality Assembly<sup>10</sup>

#### 1.4.4 Application to Research

As previously stated in the research objectives, the Flattop critical assembly was used to irradiate elements found in the earth's crust, components of detonation device, and urban construction materials. Use of a known neutron energy spectra and flux, fast neutron reaction cross sections by measuring the radioactive decay of activation products. The three main reactions seen were n-p, n-2n, and n- $\gamma$ . Examples of these reactions are shown below in figure 5.

Figure 5: Nuclear reactions n-p, n-2n, and n- $\gamma$

For gamma emitting isotopes of significant activity produced, determining the amount of activation product is simple and can be performed using NDA. Difficulty arises when activation products produced do not have significant activity, clear gamma photopeaks, or are stable preventing the use of NDA. DA must be used in these cases. The elements irradiated were aluminum (Al), gold (Au), chromium (Cr), cobalt (Co), copper (Cu), iron (Fe), iridium (Ir), nickel (Ni), lead (Pb), platinum (Pt), titanium (Ti), and tungsten (W). All of these samples are found in NIST reference alloys, concretes, and cements.<sup>11</sup> Additionally, Ti, Ir, and Au can be used to measure the fission rates of uranium and plutonium.<sup>12</sup> Historically, test shots using Orallo

incorporated Ti as an indicator of the fission fraction based on the fast neutron n-p reaction of  $^{47}\text{Ti}$  to  $^{47}\text{Sc}$ .<sup>13</sup>

In real world situations, samples collected will be in a different matrix requiring sophisticated DA to analyze isotopic composition. Samples produced from a nuclear detonation will be composed variable amounts of metal, concrete, cement, and glass. Production and characterization of melt glass standards is required matching similar environmental and detonation conditions so as to develop specific radioisotope separation methods. Examples of different synthetic melt glasses comparing environments, and different bomb designs has been produced by Nizinski,<sup>14</sup> and Molgaard.<sup>15</sup> Experimental methods need to be produced to efficiently measure isotopic prior to real world samples. Examples of sample digestion, and separation methodology using simulated melt glass was performed by Roman, and Bond,<sup>16</sup> for separating multiple 1<sup>st</sup> row transition metals.

This dissertation work, involves developing a chemical separation method for application to activated scandium ( $^{46-50}\text{Sc}$ ) from natural titanium ( $^{46-50}\text{Ti}$ ) for use in producing artificial debris. The production of radioactive scandium is very minimal as shown later in the data and requires separation and concentration to increase specific activity. The longest lived isotope produced is  $^{46}\text{Sc}$  with an 83.79 day half-life.<sup>17</sup> Improving capture cross section measurements of radioisotopes of Sc is important to the weapons stockpile in addition to use for nuclear forensics.

Additionally, this separation method developed for nuclear forensic purposes could be applied to nuclear medicine. Chemical separation methods developed for nuclear forensic purposes rely on the same principles and can be adapted for use in nuclear medicine. The Ti/Sc separation mentioned previously could be applied to separate  $^{44}\text{Ti}$  from  $^{45}\text{Sc}$  which was found useful in nuclear imaging.<sup>18,19</sup>

## 1.5 Nuclear Medicine

In the third part of the research, chromatographic separation methods were applied for use in positron emission tomography (PET). Positron emission tomography is a medical diagnostic tool that produced three-dimensional images of metabolic processes in the human body. A radionuclide tracer that emits positron is chemically bound to a biomolecule which is ingested by a patient. Different biomolecules and radionuclides tracers are used depending on where you want it to concentrate in the human body. Positron emitted from the tracer combine with electrons and annihilate into two 180 degrees 511 keV gammas. These gammas are measured in coincidence by a ring of scintillation detectors such as sodium iodide (NaI). Each measured  $\gamma$  corresponds to a slice of a total image constructed through computer analysis. PET individually or combined with computer tomography (CT) or magnetic resonance imaging (MRI) allows for details measurements of the body useful for diagnosing or determining treatment options.<sup>3</sup> An example of a PET instrument is shown below in figure 6.

Figure 6: An example of a positron emission tomography (PET) instrument<sup>20</sup>

Clinical PET imaging is used primarily for three purposes: cancer diagnosis and management, cardiology and cardiac surgery, and neurology and psychiatry. For cancer diagnosis and management, PET imaging is used to diagnose the type, the number, the primary, and the stage of a cancerous tumor. Additionally, it can be used to look for residual diseases while measuring treatment response and detecting recurrence. For cardiology and cardiac surgery, it can be used to diagnose and assess the condition of the heart such as in the case of coronary artery disease (CAD). This is needed to determine the risks of surgery, and to determine if a cardiac transplant is needed in addition to associated risks and limitations. For neurology and psychiatry, it used to diagnose brain tumors, and determine risks involved with surgery. It is also used to measure metabolic processes to diagnose cases of mental deterioration such as in the case of dementia or Alzheimer’s disease. The power of clinical PET has been shown to substantially alter patient management, through avoidance of futile aggressive therapy, high risk procedures, and improved cost effectiveness.<sup>3</sup> A reference table of costs saved by PET per life-year in different clinical procedures is shown below in table 1.

Table 1: Comparison of costs saved per year using PET by clinical procedures in 2005

Procedure	Cost/Life-Year Saved (US Dollars) <sup>3</sup>
Liver Transplant	\$43,000-250,000
Mammography (<50 years)	\$160,000
Renal dialysis	\$116,000
Chemotherapy	\$46,000
Cardiac transplant	\$27,000

Many different isotopes have been utilized previously for PET. In the past, the most prevalent were ones with short half-lives, and positron energies of ~0.5 MeV. Some common examples are shown below in table 2.

Table 2: Properties of some common positron emitting nuclides of interest<sup>3</sup>

Nuclide	$E_{\text{mode}}$ (MeV)	Half-life (Minutes)	Average Range in Water (mm)
<sup>11</sup> C	0.326	20.4	1.1
<sup>13</sup> N	0.432	9.96	1.5
<sup>15</sup> O	0.696	2.03	2.5
<sup>18</sup> F	0.202	109.8	0.6
<sup>68</sup> Ga	0.783	68.3	2.9
<sup>82</sup> Rb	1.385	1.25	5.9

All of these isotopes consist of short half-lives that range from a few minutes to a few hours. Use of these nuclides, require production and separation methods close to the treatment centers. This requires a designated cyclotron, and staff to produce the isotopes of interest followed by chemical separation prior to shipping while trying to maintain a significant activity for potential medical use. In the case of <sup>18</sup>F, one of the most common isotopes, the production, separation, and medical treatment would have to be performed under 18.3 hours (10 half-lives). Each additional treatment would require another round of production/separation.

### 1.5.1 Application to Research

To reduce the need for cyclotrons, and radiochemistry laboratories at every hospital, longer lived PET radiometals such as  $^{64}\text{Cu}$  (12.7 hours),  $^{89}\text{Zr}$  (3.26 days), and  $^{52}\text{Mn}$  (5.59 days) have become more popular.<sup>20,21</sup> Of these,  $^{52}\text{Mn}$  shows the most promise with an average positron energy of 0.24 MeV. Additionally, in the case of full time-course of treatments (2-3 week periods), only one round of production/separation for  $^{52}\text{Mn}$  is required.<sup>21</sup>

The isotope  $^{52}\text{Mn}$  has been produced either indirectly using  $^{52}\text{Fe}$  (8.3 hours)<sup>22</sup> as a radionuclide generator or directly through activation of  $^{52}\text{Cr}$ . The indirect method uses high energy  $^3\text{He}$ ,  $^4\text{He}$ , or protons onto Cr, Mn, or Ni targets to produce  $^{52}\text{Fe}$ . This method is more involved requiring purification of  $^{52}\text{Fe}$  from the targets followed by separation of  $^{52}\text{Mn}$  as it grows in. The direct method involves activation of  $^{52}\text{Cr}$  with 10-20 MeV protons (p-n reaction) followed by a chemical separation. The direct method is preferred over the indirect as it has fewer production, and separation steps. The cross section of the p-n reaction of  $^{52}\text{Cr}$  at 10.5 MeV is 98 millibarns.<sup>23</sup> It is considered a high yield route available to small biomedical cyclotrons which can use  $^{\text{nat}}\text{Cr}$  due to a 83.8% natural abundance of  $^{52}\text{Cr}$  and a small impurity formation of other Mn isotopes.<sup>22</sup>

Application of  $^{52}\text{Mn}$  PET allows for imaging the cellular processes of organ structure, function, disease, and cancer.<sup>24</sup> Use of longer lived radioisotopes makes it simpler to perform long term imaging of a system. It has also been used measure cellular processes such as  $\text{Ca}^{2+}$  uptake pathways in the brain,<sup>24</sup> and human stem cell expression.<sup>25</sup> Significant bioaccumulation has been shown in the brain, liver, kidney, and pancreas<sup>26</sup> while use of chelating agents allows for imaging of the rest of the body. Examples of chelating agents used with  $^{52}\text{Mn}$  are dipyrrodoxyl diphosphate, macrocyclic Schiff-base ligands, cyclopentadienide, and porphyrin derivatives.<sup>27,28</sup>

These chelating agents have been repurposed from contrasting agents used in MRI procedure.<sup>27,28</sup> Radiostable  $Mn^{2+}$  has previously been used in MRI to image anatomical details, and trace neural pathways.<sup>29</sup>  $Mn^{2+}$  is a paramagnetic ion that works as analog for  $Ca^{2+}$  allowing it to enter excitable cells such as cardiac or neurons through voltage gated channels. Once inside a cell, it can travel along neural axons cross synapses to different neurons. This method of measuring neural pathways with Mn is called manganese enhance magnetic resonance imaging (MEMRI).<sup>29</sup> Production and separation of  $^{52}Mn$  in the divalent oxidation state would allow for neural imaging application looking at the metabolic processes with PET and the anatomical structure with MRI.

## CHAPTER 2: CHEMICAL SEPARATIONS

### 2.1 Solvent Extraction

Solvent extraction (SX), otherwise known as liquid-liquid extraction, is a chemical extraction technique used to separate solutes between two immiscible or partially miscible solvent phases. Generally, there is an aqueous phase composed of a polar solvent such as water, acid or base and an organic phase consisting of a nonpolar solvent and extracting ligand. Additionally, modifiers may be added to each phase to aid in enhancing or suppressing extraction of a solute between layers. Difference classes of extraction ligands based on strength of the donating atom in addition to the oxidation, and ionic size of the analyte. In the case of a metal cation, a ligand dissolved in the organic phase will form a chelate with the metal at one or more sites creating a neutral species when contacted. The newly formed neutral species will have greater solubility in nonpolar solvents and will migrate across the phase boundary into the organic layer. Certain extracting ligands cannot readily complex with solutes unless aided by the addition of diluents to improve its physical properties. For example, diluents are used to aid in solubilizing solid extractants into the liquid organic phase. Alternatively, modifiers can be added to the aqueous phase to complex solutes reducing their extractability.<sup>30</sup>

In a solvent extraction system, a solute dissolved the organic or aqueous layer will distribute between phases until equilibrium. Usually the system requires mixing to increase surface area contact thereby promoting distribution of the analyte. At system equilibrium, the ratio of solute concentration in the organic phase  $[A]_{\text{org}}$  to the solute concentration in the aqueous phase  $[A]_{\text{aq}}$  is known as the distribution ratio  $D$  of the solute concentration. The distribution ratio equation is shown below as equation 2.<sup>30</sup>

$$D = \frac{[A]_{org}}{[A]_{aq}} \quad (2)^{30}$$

The distribution ratio is always expressed as the ratio of the organic phase concentration to the aqueous phase concentration irrespective of each layer's density. In many solvent extractions, multiple solutes are distributed between the two immiscible phases and are designated with the subscript A, B, C, etc. If the distribution ratio of each solute differs, then each solute can be separated from the others by a single or multistage solvent extraction. The separation factor  $SF$  is the term used to designate the separation capability of two solutes in a solvent extraction system. The equation for separation factor is below as equation 3.<sup>31</sup>

$$SF_{AB} = \frac{D_A}{D_B} \quad (3)^{31}$$

Alternatively, the decontamination factor DF can be determined to show the level of contamination of one analyte in regard to another in each separation fraction. This is performed using the ratio of one analyte concentration to another in each separation or elution fraction.<sup>32</sup>

In many practical applications of solvent extraction, it is common to use the term percent extraction  $\%E$  which refers to the extraction potential of a solute between two immiscible phases in a system. The equation for percent extraction is below as equation 4.<sup>30</sup>

$$\%E = \frac{100 * D}{(1 + D)} \quad (4)^{30}$$

Use of this equation only occurs when a reasonable percent of the desired solute is extracted in one solvent extraction step. For example, when the distribution ratio  $D$  equals 1 then the solute is equally distributed between both phases.<sup>30</sup>

Different vessels such as a separatory funnel or test tube is used to separate the two phases. Generally, the organic phase has a lower density and will form the upper layer while the aqueous phase has a higher density and will form the lower layer.<sup>30</sup> There is sometimes a third phase that forms at the phase boundary which is a emulsion or colloid formation. This is caused by the suspension of insoluble particles (dispersed phase) in another substance (continuous phase). A schematic of the three phases is shown below in figure 7.<sup>33</sup>

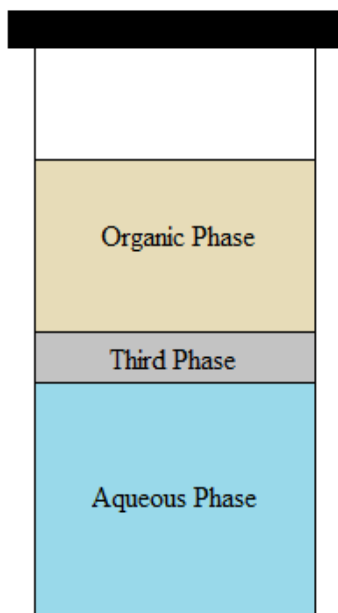

Figure 7: Schematic of solvent extraction phases in a test tube

Phase disengagement or removal of the third phase is essential to extraction of the solute between phases. There are many causes to third phase formation such as incompatibility of solvents, higher concentration of extraction, or impurities in the system.<sup>34</sup> Third phase can be reduced/removed by the adding an aromatic diluent and or a modifier such as a strong Lewis base (e.g. octanol or tributyl phosphate).<sup>30</sup>

## 2.2 Extraction Chromatography

Extraction chromatography (EXC) is chemical separation technique based on solvent extraction composed of an inert support, a stationary phase, and a mobile phase. The inert support consists of porous silica or an organic polymer usually ranging from 50 to 150  $\mu\text{m}$  in diameter. The stationary phase is comprised of a liquid extractant sorbed to the surface of the inert support which extracts analytes from the mobile phase. The mobile phase is a aqueous polar phase consisting usually of dissolved solute in an acid matrix.<sup>30</sup> Similar to solvent extraction, diluents may be added to aid solubilization of the extracting ligand while increasing the hydrophobicity of the stationary phase. Other modifier such as complexants may be added to enhance selectivity of an analyte or to promote stripping of strongly retained metal ions from a column.<sup>35</sup> Extraction chromatography is preferential to SX due to a great reduction in organic waste produced which is compounded when dealing with radionuclides.<sup>30</sup>

In EXC, the volume distribution ratio  $D$  measured in a solvent extraction system (SX) can be converted to the number of free column volumes to peak maximum defined as  $k'$  (the resin capacity factor) using the volume ratio of the stationary  $V_s$  and mobile phase  $V_m$ . This is shown below in equation 5.<sup>35</sup>

$$k' = D \cdot \frac{v_s}{v_m} \quad (5)^{35}$$

In EXC systems, it is simpler to measure the weight distribution  $D_w$  and convert the volume distribution  $D$  or resin capacity factor  $k'$ . The term  $D_w$  is determined by measuring the amount analyte retained for a known weight of resin and volume of aqueous solution. The equation for measuring  $D_w$  is shown below in equation 6.<sup>35,35</sup>

$$D_w = \frac{A_0 - A_s}{A_s} \cdot \frac{V}{w} \quad (6)^{35}$$

The term  $A_0$  refers to the initial activity or analyte concentration in the known volume before extraction while  $A_s$  refers to the final activity or concentration after extraction. The expression  $A_0 - A_s$  refers to the activity or concentration sorbed onto a known weight of resin  $w$  in grams using a known total volume  $V$  of solution in mL. Conversion of the weight distribution  $D_w$  to the volume  $D$  is shown below as equation 7.

$$D = D_w \cdot \frac{d_{extr}}{WF} \quad (7)^{35}$$

The term  $d_{extr}$  refers to the extractant density and  $WF$  refers to weight fraction of extractant loading in grams per grams of resin. Substituting equation 7 into 5 provides a direct relationship between the weight distribution and  $k'$  and is shown below as equation 8.<sup>35,36</sup>

$$k' = D_w \cdot \frac{d_{extr}}{WF} \cdot \frac{v_s}{v_m} \quad (8)^{35,36}$$

Achieving an optimal separation in EXC means minimizing band broadening to prevent early breakthrough while avoiding disproportionate cross-contamination of the analytes being separated. Poor column efficiency through significant band broadening can negate a very selective extraction resin. Column efficiency can generally be expressed in terms of height equivalent to a theoretical plate (HETP). Height equivalent to a theoretical plate is a concept based on the length of the column, the width of the peak, and volume of eluent. Each theoretical plate represents a step or stage in the multi-stage extraction process where equilibrium is established between the mobile and stationary phase. Increasing the number of plates for a set column length allows for an improvement in analyte separation.<sup>37</sup>

In extraction chromatography, the efficiency of a column is determined by flow phenomena, diffusion of the mobile phase with respect to the stationary phase, and extraction kinetics of the ligand. Flow phenomena deals with eddy diffusion which are variations in the analytes phase flow path affecting band broadening. Diffusion to the stationary phase refers to analytes ability to diffuse back and forth from the mobile phase to the stationary phase. While extraction kinetics refers to rate at which the extractant can electrochemically bind to analytes diffusing through the column. Column efficiency additionally depends on the size of the resin particles, the porosity of the support, the extractant loading and mobile phase velocity, and the operating temperature.<sup>37</sup>

## 2.3 Application of Separation Methods

### 2.3.1 Extraction of Scandium from Titanium

In this research, EXC will be used to extract scandium from titanium. Shown later in chapter 4, fast neutron activation of titanium produces scandium in quantities less than 1% of the initial mass. In any separation method, it is simpler, faster, and requires less extracting ligand to extract a smaller quantity of analyte from the initial bulk concentration.

Extraction chromatography was used to separate Sc and Ti based on their difference in oxidation states and ionic radii in aqueous solution. Neutral scandium has an electronic configuration of  $[\text{Ar}]3d^14s^2$  and acts as a strong reducing agent in aqueous solutions primarily forming  $\text{Sc}^{3+}$ .<sup>38,39</sup> The diameter of the neutral Sc radius is 162 pm but decreases to 89 pm in trivalent form. In hydrochloric acid, formation of  $\text{ScCl}_3$  becomes the predominant species from 1 to M up while in nitric acid,  $\text{Sc}(\text{NO}_3)_3$  primarily forms as the nitrate concentration increases. At very low acid concentrations speciation will split between the hydroxide, oxide, and acid ion form.<sup>38,40</sup> Alternatively, neutral titanium has an electronic configuration of  $[\text{Ar}]3d^24s^2$  and primarily is in the divalent form  $\text{Ti}^{2+}$  or tetravalent  $\text{TiO}^{2+}$  form in solution under a pH of 2 at a voltaic potential above -1.5 volts.<sup>38,39</sup> The diameter of neutral Ti radius is 147 pm but decreases to 60.5 pm in tetravalent and 86 in divalent form.<sup>38,39</sup> In hydrochloric acid, Ti remain in the oxide form  $\text{TiO}_2$  while at very low concentrations until  $\sim 9$  M or higher when it may form the complex  $\text{TiCl}_6$ . In nitric acid,  $\text{TiO}_2$  may not react with nitrate unless the concentration is high forming  $\text{Ti}(\text{NO}_3)_4$ .<sup>38,41</sup>

Separation methods using ion exchange, solvent extraction and extraction chromatography have been used previously to separate Sc and Ti. Cation and anion exchange columns using AG MP-50,<sup>42</sup> Dowex 50 X8,<sup>43</sup> and Dowex 1 X8<sup>44</sup> were able to separate scandium from titanium with

a separation factor up to 90 and recoveries from 50 to 90%. The main issue in using ion exchange is the significantly larger volume of acid (orders of magnitude) needed for column elution producing significantly more waste. Solvent extraction using tributyl phosphate (TBP),<sup>42,43</sup> Trioctylamine (TOA),<sup>45</sup> di(2-ethyl-1-hexyl) phosphoric acid (HDEHP),<sup>46</sup> and N,N,N',N'-tetra-n-octyldiglycolamide (TODGA)<sup>47</sup> showed better separation factors up to ~1000 with scandium recovery greater than 90% Sc. Similar to ion exchange, solvent extraction produced large amount of organic waste in each separation which is significantly costlier if radionuclides are involved. Additionally, the HDEHP ligand was used in a EXC column and recovered greater than 98% of the initial scandium. However, this method did not determine the titanium contamination.<sup>48,49</sup> Use of EXC resins instead of ion exchange and solvent extraction would allow for a potentially high recovery while minimizing organic and aqueous waste.

In addition to getting a large separation factor, analyte recovery, and minimizing waste, the separation process needs to be quick and efficient in the case of a nuclear detonation. For this work, commercial available resins using ligands previously shown to separate scandium from titanium were employed. Ln 1 (LaNthanide), and DGA resin produced by Eichrom technologies relying on the HDEHP ligand and TODGA ligand have been shown to previously separate these species.

The Ln 1 resin is comprised of 40% (w:w) di(2-ethyl-1-hexyl) phosphoric acid (HDEHP) sorbed onto Amberchrom CG-71 beads (50-100 $\mu$ m).<sup>50,51</sup> The structure of the ligand HDEHP is shown below in figure 8.

Figure 8: HDEHP ligand structure

Ln 1 resin, Ln 2 and Ln 3 vary in the number of oxygen atoms bonded between the phosphate and carbon chains. Ln 1, shown above has four oxygen atoms bound to the phosphate while Ln 2 has only three and Ln 3 has only two.<sup>51,52</sup> Having more oxygen atoms bound to the phosphate group in the case of Ln 1 allows for greater resonance and a stronger extraction potential than Ln 2 and Ln 3.

Two different coordination forms have been theorized for the complexation between HDEHP ligands and a trivalent metal. The first involves the monodentate complexation of six ligands around a single metal center acting as dimer pairs through shared hydrogen bonding while the second involves the bidentate complexation of six ligands shared between two metal centers ( $M_2HDEHP_6$ ).<sup>52,53</sup> Understanding of the coordination forms allow for prediction of the coordination number between the metal ion and ligands. Both structures are shown below in figure 9.

Figure 9: Trivalent metal complexation structure using HDEHP ligands<sup>52,53</sup>

DGA resin is composed of 40 wt.% N, N, N', N'-tetra-n-octyldiglycolamide (TODGA) sorbed onto Amberchrom CG-71 beads (50-100 $\mu$ m).<sup>54</sup> The structure of the ligand is shown below in figure 10.

Figure 10: TODGA ligand structure

DGA has been shown to be tridentate in configuration for actinides and lanthanides, complexing trivalent metal ions through two carbonyl oxygen donors and one ether oxygen donor. Three stable five-membered chelate rings form between each of the three TODGA ligands and one metal ion forming a coordination number of 9.<sup>55</sup> Although, Sc does not possess f shells, work performed by Zhu<sup>47</sup> using solvent extraction and TODGA shows Sc(III) coordinating with an average of 2.6 ligands. This may be due some ligands only binding with two oxygen atoms instead of three.

### 2.3.2 Extraction of Manganese from Chromium

Similar to the Sc/Ti separation, Mn produced from Cr will have a significantly smaller atomic fraction and will likely require less material to extract. Separation of the two was performed using solvent extraction to determine potential ligands followed by EXC to reduce waste. The separation was based on the difference in oxidation states and ionic radii in aqueous solution. Neutral manganese has an electronic configuration of  $[\text{Ar}]3d^54s^2$  and is predominantly  $\text{Mn}^{2+}$  in acid concentrations below a pH of 8. The neutral radius is 127 pm but decreases to 67 pm in divalent form. In hydrochloric acid, Mn will form different chloride species as the acid concentration increases. At very low acid (less than 1 M), Mn will form oxides or hydroxides, from 1 to 4 M  $\text{MnCl}_2$  will be the dominant form, and from 6 to 12 M  $\text{MnCl}_3^-$  will be the dominant form. In nitric acid, little complexation will occur and Mn will likely remain in the oxide or hydroxide form.<sup>38,56</sup> Alternatively, neutral chromium has an electronic configuration of  $[\text{Ar}]3d^54s^1$  and is primarily  $\text{Cr}^{3+}$  in aqueous solutions below a pH of 4. The neutral radius is 128 pm and decreases to 61.5 pm in trivalent form. Separation of divalent Mn from trivalent Cr can be performed in acidic conditions under a pH of 4 with a voltaic potential between -0.6 and 1.4 volts.<sup>38,39</sup> In hydrochloric or nitric acid, Cr speciation more complicated as the Cr strongly binds with water forming the species  $\text{Cr}(\text{H}_2\text{O})_6^{3+}$   $\text{Cr}_2\text{O}_3$  preventing formation of anionic complexes due to strong binding of water.<sup>41</sup>

Separation methods using ion exchange and solvent extraction were used previously to separate Mn from Cr. Cation and anion exchange columns using Dowex 50Wx8,<sup>57</sup> and Ag-1x8<sup>26</sup> were used to separate Mn(II) from Cr(III) with separation factors up to 50, and recoveries from 73 to 99% but require significantly larger quantities of acid to run a column. Solvent extractions using methyltrioctylammonium chloride (Aliquat 336),<sup>58</sup> tris(2-ethylhexyl)phosphate,<sup>59</sup> and

hexaacetateocalixarene<sup>60</sup> demonstrated separation factors from 10 to 50 using Cr(VI) and Mn(II) with analyte recoveries from 50 to 80%. The optimal method shown by Lahiri<sup>61</sup> was to use the ligand trioctylamine (TOA) to separate Mn(II) from Cr(III) with a separation factor >10,000. Although, significant organic waste is produced in SX, it is necessary to determine ligand extraction potential and was explored prior to development of a EXC resin.

The ligand TOA consists of a nitrogen atom bonded to three R groups consisting of eight carbon chains. The nitrogen center of TOA acts as an electron donor extracting divalent species in the case of Mn<sup>2+</sup>. The structure of the TOA ligand is shown below in figure 11. The equilibrium expression for extraction of Mn(II) into the organic from the aqueous phase is shown below in figure 12.

Figure 11: Trioctylamine (TOA) ligand structure

Figure 12: Equilibrium expression for the extraction of Mn(II) into the organic phase using TOA<sup>62</sup>

In hydrochloric acid, ~2 ligands of TOA are needed to extract Mn(II) from the aqueous to the organic phase.<sup>56</sup> Opposed to the Sc/Ti extraction, the extraction here is unidentate and should not vary in the number of ligands of extractant coordinated to the metal center. In the Sc/Ti system, both Ln and DGA resin use ligands that complex using bidentate configuration which may cause a variation in measured ligand coordination while in solution. Instead of complexing with three bidentate ligands, two ligands may attempt to partially coordinate with the metal center instead of a single fully coordinated ligand creating a temporary four ligand coordination. This should not occur in the Mn/Cr separation as the TOA ligand coordination is unidentate.

## CHAPTER 3: METHODOLOGY

### 3.1 Materials

In this research, all standards used (Ti, Sc, Cr, and Mn) were ICP-MS certified reference grade from British Drug Houses (BDH). All acid solutions were prepared from ARISTAR Plus grade (metal impurities <1 ppb) nitric and hydrochloric acid from BDH. All acids were titrated prior to use in any experiment using 0.1 N sodium hydroxide solution and phenolphthalein indicator solution from Sigma Aldrich. All solutions were prepared using 18.2 M $\Omega$ .cm deionized water from a Millipore or Pall water purification system. All pipetting performed used Eppendorf pipettes and tips from VWR. All mixing or sample agitation performed used Labquake™ shaker tables from Thermo Scientific. All plastic vials (2 mL, 5 mL, 15 mL, or 50 mL) used were composed of polypropylene from VWR. All laboratory glassware, glass bottles used for chemical storage, and glass scintillation vials were composed of borosilicate glass from VWR.

All high purity germanium measurements performed used a 5 mL solid in plastic liquid scintillation vial source (84912-602) for energy calibration from 59.5 to 1836.1 keV. The source was purchased from Eckert & Ziegler.

In the solvent extraction work performed, Trioctylamine  $\geq 97.0\%$  ligand, and 1-Octanol  $\geq 99.0\%$  was purchased from TCI America. ACS grade cyclohexane used was purchased from BDH. Any deviation in solvent extraction materials used will be described in chapter 7.

In the batch contact studies performed, bulk 50 – 100  $\mu\text{m}$  particle size Ln 1, and DGA resin was purchased from Eichrom Technologies. Additional details about these resins are described in chapters 2, and 5. All TOA resins used were specially produced from Triskem International and are discussed further in chapter 6. Polypropylene spatulas for weighing resin, and BD Luer-lok tipped syringes used for filtration were purchased from VWR. Acrodisc® syringe filters using

0.45  $\mu\text{m}$  polytetrafluoroethylene membranes were purchased from Pall Life Sciences. Any deviation in batch contact study materials used will be described in chapters 5, and 8.

In the column studies performed, 2 mL columns, 25 mL extension funnels, and a vacuum system with associated parts (Part# AR-12-Box) was purchased from Eichrom Technologies. Any deviation in column study materials used will be described in chapter 6.

## **3.2 Cross Section Determination using Flattop Criticality Benchmark**

### **3.2.1 Experimental Procedure**

An HPGe well detector was calibrated using a water standard matching the geometry, volume, and container type of each activation sample. A background activity measurement was taken of the room for one and twenty-four hours using a blank or empty plastic vial matching the geometry, volume, and container of each activation sample. A comprehensive nuclide library of potential activation products including  $\gamma$  decay ratios, and energies was prepared for all metal foils planning to be irradiated.

After each neutron activation run, individual activation foil solutions were measured for one hour to determine short-lived radioisotope production from the run. This was followed by a twenty-four hour measurement to get a more accurate and precise activity value for each radioisotope produced.

### **3.2.2 Flattop Data Analysis**

#### **3.2.2.1 Gamma Spectra Analysis**

Data analysis of each gamma measurement was performed using the Genie 2000 gamma software by Canberra. Calibration of the instrument involved taking a measurement of the water standard for a few hours followed by calibration of the spectra using the certificate energy distribution and efficiency. Each activation foil measurement spectra were processed using the

peak locate and area functions where peaks in a spectrum with counts above the baseline were identified, followed by integration and summation of all counts within the energy region. The area correction function was used subtract background counts from previously measured background spectra matching volume, geometry, and measurement time. Each spectrum was then calibrated for efficiency and energy distribution by channel using the previously made calibration file followed by nuclide identification on a list of proposed elements being activated. The nuclide identification process involves matching gamma peaks by their energy and decay ratio to provide a total weighted activity and uncertainty in  $\mu\text{Ci}$  for each isotope.

### 3.2.2.2 Flux and Cross Section Determination

Cross section determination for each radioisotope produced was performed using a variation of the neutron activation equation shown in equation 1. Instead of solving for the rate of production  $R_p$ , the cross section  $\sigma$  for each isotope produced can be determined using the activity right after irradiation (time zero)  $A$ , the flux of neutrons  $\Phi$ , the target density  $n$ , the length of irradiation  $t$ , and the decay constant for said isotope  $\lambda$ . The full equation is shown below in equation 9.

$$A = \Phi n \sigma [1 - e^{(-\lambda t)}] \quad (9)^{63}$$

For this work, the activity  $A$  at time zero was calculated using the measured activity of each isotope produced or activity final  $A_f$ , using the standard radioactive decay equation shown below in equation 10. In equation 10, the time variable  $t$  refers to the total length of time after irradiation (time zero) to the end of the measurement.

$$A_f = Ae^{(-\lambda t)} \quad (10)^{63}$$

To solve for the cross section  $\sigma$  of each isotope, the flux of neutrons  $\Phi$ , and target density  $n$  are still needed. The target density was based on the total number of isotope atoms in a known target mass divided by the surface area of the target that was determined using the standard density of the metal foil or salt. Certificate information was not provided for each run so it was assumed that each target was without impurity and cubic in shape.

To determine the neutron flux in this calculation, the only information known was that the power level was consistent for each run<sup>64</sup> and that an Au foil was placed in the same relative position to the <sup>235</sup>U core, which has been used previously to calculate a <sup>235</sup>U fission rate. This <sup>235</sup>U fission rate or neutron flux can be determined based on the production of <sup>198</sup>Au from the nuclear reaction <sup>197</sup>Au(n,  $\gamma$ )<sup>198</sup>Au using a known amount of <sup>197</sup>Au target.<sup>12</sup> In each Flattop run, power levels were measured ensuring consistency between all runs,<sup>64</sup> it is fair to assume that the average of these fluxes would be useable to determine individual nuclear reaction cross sections for each foil activated. For this purpose, a fission spectra cross section average was taken from the Japanese Atomic Energy Agencies JENDL-4.0 program. Each cross section determined beside Au was compared to cross sections calculated from different runs in addition to fission spectra cross section averages determined by the JENDL-4.0 program if available.

### **3.3 Solvent Extraction Research**

#### **3.3.1 Solvent Extraction Study**

##### **3.3.1.1 Experimental Procedure**

Two solvent extraction studies based on previous methods used in literature were performed to measure the extraction potential of a analyte by varying the ligand or analyte concentration.<sup>59,61,62</sup> In both studies a known volume and concentration of 1:1 ratio of ratio organic to aqueous phase was added to a vial. The organic phase consisted of TOA ligand in cyclohexane solvent and 1-octanol to reduce third phase formation. The aqueous phase consisted of a known concentration of Cr and Mn analyte in a set hydrochloric or nitric acid concentration. Each vial containing both phases was mixed on a Labquake shaker table for set period to promote mixing. An aliquot of the aqueous phase was removed after mixing to measure the loss of analyte to the organic phase. Samples from the aqueous phase were diluted and analyzed using an ICP-AES or ICP-MS further detailed in section 3.6. Specific experimental details are described in chapters 5 and 7.

##### **3.3.1.2 Data Analysis**

The analyte concentration measured in the aqueous phase was subtracted from the total initial concentration to determine the analyte concentration in the organic phase. The distribution ratio  $D$ , separation factor  $SF$ , and percent extraction %E were calculated using equations 2, 3, and 4 from chapter 2.

### **3.3.2 Kinetic Study**

#### **3.3.2.1 Experimental Procedure**

The kinetic study procedure duplicated the solvent extraction procedure in section 3.3.1.1 using the optimal ligand and acid concentration determine while varying the mixing time needed to test the extraction kinetics. Specific experimental details are described in chapters 5, and 7.

#### **3.3.2.2 Data Analysis**

The data was analyzed by the same method shown in section 3.3.1.2.

### **3.3.3 Third Phase Formation Study**

#### **3.3.3.1 Experimental Procedure**

The third phase formation procedure duplicated the solvent extraction procedure in section 3.3.1.1 without any analyte in the aqueous phase and only TOA ligand and cyclohexane in the organic phase. After mixing each solution, drops of 1-octanol were added to each vial using a Pasteur pipette followed by mixing. This was repeated until the third phase disappeared. The number of drops were recorded for each ligand/acid concentration. Using the same Pasteur pipette, the average mass of one drop of 1-octanol was weighed on a laboratory scale. Specific experimental details are described in chapters 5, and 7.

#### **3.3.3.2 Data Analysis**

The volume of 1-octanol needed to remove the third phase in each acid/ligand concentration was determined by dividing the density of 1-octanol by the mass of 1-octanol (number of drops) used to remove the colloid or third phase formation.

## **3.4 Batch Contact Research**

### **3.4.1 Batch Contact Studies**

#### **3.4.1.1 Experimental Procedure**

The batch contact procedure adapted for this work was based on previous literature methods.<sup>35,36,65,66</sup> A known mass of resin was added to a vial, which was preconditioned using a set volume of acid. The vial was mixed on a Labquake shaker table for a set period expediting the diffusion of the aqueous phase into the interstitial space between each resin bead. The swollen resin was left for another set period ensure it reached equilibrium. A stock solution of analyte in a set hydrochloric or nitric acid matrix was added to each resin vial followed by mixing for another set period. The solution of each vial was filtered into a new clean vial by filtration using a syringe and 0.45  $\mu\text{m}$  PTFE filter. Samples from the aqueous phase were diluted and analyzed using an ICP-AES or ICP-MS further detailed in section 3.6. Specific experimental details are described in chapters 5, and 7.

#### **3.4.1.2 Data Analysis**

The weight distribution  $D_w$  followed by conversion to  $k'$  was determined equation 6, 7, and 8 in section 2.2.

### **3.4.2 Kinetic Batch Contact Study**

#### **3.4.2.1 Experimental Procedure**

The kinetic batch contact study replicated the batch study procedure per section 3.4.1. In the kinetic study, each batch study was replicated using a varied mixing time after the spike addition step.

### **3.4.2.2 Data Analysis**

The data analysis method is described in section 3.4.1.2.

### **3.4.3 Batch Contact Volume Correction**

#### **3.4.3.1 Experimental Procedure**

For each resin tested, two sets of vials labelled 1<sup>st</sup> and 2<sup>nd</sup> set were weighed for each acid concentration. Set mass of resin was added to each vial in the 1<sup>st</sup> set followed by each vial being weighed again. A known volume of for each acid concentration was added to each vial in the 1<sup>st</sup> set followed by each vial being weighed again. Each vial in the 1<sup>st</sup> set was placed on mixing table for a set period. The contents of each vial were filtered using a syringe and 0.45  $\mu\text{m}$  PTFE filter into a designated vial from the 2<sup>nd</sup> set. Each vial in the 2<sup>nd</sup> set was weighed again. Specific experimental details are described in chapters 5, and 7.

#### **3.4.3.2 Data Analysis**

The difference in mass between the initial acid volume in the 1<sup>st</sup> vial set and the final acid volume in the 2<sup>nd</sup> vial set divided by the mass of resin in each vial gives the mass loss of for a specific acid concentration. The volume lost is determined from the specific density for that acid concentration. Specific experimental details are described in chapters 5, and 7.

## **3.5 Column Studies**

### **3.5.1 Gravity Column Studies**

#### **3.5.1.1 Experimental Procedure**

The gravity column studies performed were based on previous work by Horwitz.<sup>32,33,59</sup> Elution volumes in a column are based on the free column volume for a specific set up and required determination. A set amount of resin was wet using DI water in a vial and allowed to swell. After sufficient time, the Eichrom column was filled with DI water and the swelled resin was added dropwise allowing the system to settle by gravity. The resin was added dropwise to reduce formation of trapped air bubbles within the column. The height of the resin was measured, and glass wool was added to prevent movement of the resin surface as additional liquids were added. Excess DI water was drained until the solution level was in line with the bed height. The number of DI water drops from the column were counted over time to determine a flow rate.

To determine the FCV, a small volume of acid was added to the top of the resin bed and was eluted off the column in drops. Each drop was collected into a pre-weighed container with a piece of litmus paper touching the surface. The litmus paper became acidified when the acid dripped through the column and the volume collected was deemed one FCV for this system.

The set up for the gravity column study is similar to measuring the FCV. A set amount of swelled resin at an acid concentration and type matching the load solution is added to a column filled with DI water. Glass wool is added to the top of the wet slurry bed. Each column was preconditioned/washed using 5-10 FCVs of acid matching the load solution. A load solution containing the proper analyte concentration in acid was added to the column followed by collection of drops in separate vial fractions. A wash fraction of matching acid concentration was added to ensure complete elution of the analyte into the 1<sup>st</sup> set of vial fractions. In the case of multiple

analytes, the column can be reconditioned by washing with a different acid concentration and matrix to cause elution of other analytes. Samples from the aqueous phase were diluted and analyzed using an ICP-AES further detailed in section 3.6.1. Specific experimental details are described in chapters 6.

### **3.5.1.2 Data Analysis**

Analyte concentration in each fraction were measured to determine an elution profile or distribution of the analyte. Recovery of the analyte was determined by summing the total analyte concentration recovered.

## **3.5.2 Vacuum Column Studies**

### **3.5.2.1 Experimental Procedure**

The vacuum column procedure used was based on previous literature methods.<sup>35,36,66-68</sup> A vacuum box system from Eichrom was set up where only one column hole was left unsealed. The spout on the side of the vacuum box was connected to a pressure gauge/regulator connected to a vacuum system or outlet by rubber tubing. A pre-packed resin cartridge from Eichrom was connected to the unsealed column hole atop the vacuum box. A syringe was connected to the top of the pre-packed cartridge. A sample holder was placed in the box to collect elution fractions. The vacuum was turned on to elute each fraction and turned off to change elution fraction containers. The prepacked cartridge was conditioned using a set volume of acid matching the load solutions concentration and matrix. A load solution containing analytes was added to the syringe followed by elution through the column into a separate container. Another volume of clean acid matching the load solution was added to the column to elute the analyte of interest off the column. For multiple analyte solutions, another known volume of acid different from the load solution was used to strip off different analytes. These column studies were repeated in triplicate at different

flow rates. Samples from the aqueous phase were diluted and analyzed using an ICP-AES or ICP-  
Ms further detailed in section 3.6. Specific experimental details are described in chapters 6.

### **3.5.2.2 Data Analysis**

The concentration of analyte in each fraction was measured to determine analyte recovery  
from the column.

## **3.6 Instrumentation**

### **3.6.1 Inductively Coupled Plasma Atomic Emission Spectroscopy (ICP-AES)**

#### **3.6.1.1 Theory**

The ICP-AES is an instrument used to measure UV-Visible light produced by rapid de-  
excitation of an electron from a higher electronic state to their ground state. This was performed  
using a plasma source known as an ICP torch made of three concentric quartz tubes streams argon  
gas, which is ionized using an induction coil. Ionization of the argon gas occurs through used of  
a radio frequency-initiated spark using a tesla coil. The interactions of ions and flow of charge in  
the gas causes the plasma to form and heat. Samples are introduced as liquids and pumped into a  
nebulizer, which aspirates the solution transporting droplets into a spray chamber. As these  
droplets enter the plasma, electrons in the outer shells of each element in the sample are excited to  
higher energy states. Relaxation of these electrons causes emission of UV-Vis light characteristic  
of the elements in the sample. The spectrometer acts to selectively grate or disperse light of interest  
into a photomultiplier tube (PMT) detector. The intensity of the light that interacts with the PMT  
is converted to electrical signal corresponding to the concentration of that element in the  
sample.<sup>69,70</sup>

### **3.6.1.2 Analysis Method**

A Perkin Elmer Optima 7000 (CSU), 8000 (UNLV) and Thermo Scientific ICAP 6500 Duo (LANL) was used to analyze samples in chapters 5, and 6. The accompanying Syngistix software included in the instrument was used for data acquisition and analysis. For each study, an aliquot from each sample added to 15 mL centrifuge vial and diluted to an analyte concentration range of 1-100 ppm using 2% v/v HNO<sub>3</sub>. A 2% v/v HNO<sub>3</sub> nitric blank solution and set of 5 calibration solutions ranging from 1-200% of the dilute analyte concentration were made from analyte standards listed in sec 3.1. These were used as standards to produce a calibration curve for comparing the intensity measured for each analyte in the sample solutions. Additional analyte standards at 100% of the dilute analyte concentration were placed through the sample run order to account for instrumental drift over time. Additional experimental details are described in chapters 5 and 6.

## **3.6.2 Inductively Coupled Plasma Mass Spectrometry (ICP-MS)**

### **3.6.2.1 Theory**

The ICP-MS is an instrument used to measure elemental or isotopic abundance of analytes in a sample by ionization followed by separation based on the mass to charge ratio. An introduction system involving ICP, and nebulizer detailed above in section 3.6.1.1 is used to bring aliquot of solution from sample vials to the plasma for ionization. Ions produced in the plasma will travel through a set of magnetic and electrostatic analyzers such as a quadrupole, which through use of a RF field will separate ions by their mass to charge ratio. These ions of interest will travel through a filter grate and interact with a semiconductor array such as a discrete dynode detector. The intensity of each isotope measured will be amplified through secondary

electron multiplication and converted to a electrical signal corresponding to the concentration of the isotope in the sample.<sup>69</sup>

### **3.6.2.2 Analysis Method**

A Perkin Elmer NexION 350 (CSU) and ELAN DRC II (UNLV) ICP-MS was used to analyze samples chapters 7, and 8. The general analysis method is shown above in section 3.6.1.2. Additional experimental details are described in chapters 7, and 8.

### **3.6.3 High Purity Germanium (HPGe) Well Detector**

#### **3.6.3.1 Theory**

An HPGe well detector is primarily used to measure  $\gamma$  or x rays through use of a well capacity with near  $4\pi$  geometry. The ideal energy range for radiation detector is 20 keV up to 10 MeV.<sup>65</sup> In a standard system, a depleted region up to a thickness of a few centimeters is used to absorb radiation. Under a reverse bias, an electric field extends over this region causing charge carriers (holes and electrons) produced by the interaction of photons with the depleted volume to migrate toward the anode or cathode. The measured signal at the electrodes is proportional to the energy deposited in the depleted volume by the incoming photon. This charge is converted into a voltage pulse through the system preamplifier. Additionally, each germanium system needs to be cooled such as through use of liquid nitrogen to reduce the thermal generation of charge carrier due to a low band gap.<sup>69,71,72</sup>

#### **3.6.3.2 Analysis Method**

An HPGe well detector from Canberra was used to measured samples in chapter 4. The analysis method is shown above in section 3.2.2. Additional experimental details are described in chapter 4.

## **CHAPTER 4: DETERMINATION OF FAST NEUTRON CROSS SECTIONS USING ELEMENTS IRRADIATED ON THE FLATTOP CRITICALITY BENCHMARK**

### **4.1 Introduction**

In this experiment, several elements were irradiated using fast neutrons in an attempt to simulate the effects of a nuclear detonation. A series of irradiation runs were performed using the Flattop Critical Assembly Benchmark on the Nevada National Security Site under controlled conditions such as neutron flux and length of irradiation. The focus of these experiments were to irradiate elements found in the urban environment and used in nuclear device components using a neutron flux and spectra similar to a device using HEU. In the form of metal foils or salts, samples were activated by fast neutrons producing activation products based on a specific nuclear reaction cross section. Measurements were taken of activation products to determine the specific activities for each isotope produced. Based on the known conditions of the irradiation, the activity a time zero (end of irradiation) can be determined and further used to determine specific nuclear reaction cross sections for each activation product. However, many of the specific details about the irradiations were not publically available so a series of academic calculations were performed to determine cross sections instead.

### **4.2 Materials**

All activation solutions consisted of individual elemental samples (foil or salt) dissolved in clean acid to a volume of 5 mL in 5 mL plastic vials. All other materials used are described in section 3.1.

## 4.3 Experimental Procedure

### 4.3.1 Metal Foil Measurements

The general procedure used is shown in section 3.2.1. The HPGe well detector was calibration using a 5 mL water standard matching the same volume, geometry, container type as each activation sample. A background activity measurement was taken of the room at one and twenty four hour intervals using an empty 5 mL plastic vial matching the geometry, volume, and container type used for each activation product solution. A comprehensive nuclide library of potential activation products including gamma decay ratios, and energies was prepared for all metal foils planning to be irradiated.

After each neutron activation run, individual activation foil solutions were provided in 5 mL vials and were measured for one hour intervals to determine short lived radioisotope production from the run. This was followed by a twenty four hour measurement to get a more accurate and precise activity value for each radioisotope produced. The process of measuring foils followed by subsequent calculations occurred on four separate occasions. A list of all elements irradiate by run is shown in table 3.

Table 3: Elements irradiated using the Flattop Benchmark Critical Assembly

Element Irradiated	Run 1 March 2014	Run 2 October 2014	Run 3 March 2015	Run 4 June 2015
Au (Gold)	X	X	X	X
Co (Cobalt)				X
Cr (Chromium)				X
Fe (Iron)		X		
Ir (Iridium)	X		X	
Ni (Nickel)		X		
Pb (Lead)				X
Pt (Platinum)	X		X	
Ti (Titanium)	X	X	X	
W (Tungsten)				X

A list of properties for each target irradiated including mass, chemical form, chemical composition and isotope composition for each run is shown below in tables 4, 5, 6, and 7. It was assumed that each target was 100% pure as no certificate information was provided.

Table 4: Target properties of elements irradiated in run 1

Target Activation Element	Target Mass (mg)	Chemical Form	Chemical Composition	Isotopic Composition <sup>73</sup>	Atom Percent Fraction <sup>73</sup>
Au	305.9	metal foil	natural	Au-197	1.00
Ir	229.9 (69.1 mg of Ir)	K <sub>2</sub> IrCl <sub>6</sub> salt	natural	Ir-191	0.37
				Ir-193	0.63
Pt	109.4	metal foil	natural	Pt-192	0.01

### 4.3.2 Data Analysis

A sample calculation with description of assumptions used is shown in appendix A.

#### **4.3.2.1 Gamma Spectra Analysis**

The gamma spectra data analysis method used to process gamma spectra on the Genie 2000 Software is described in section 3.2.2.1.

#### **4.3.2.2 Flux and Cross Section Determination**

The general method for flux and cross section determination in greater detail is outlined in section 3.2.2.2. Fission spectra cross section values for the n-2n and n- $\gamma$  reactions for  $^{196}\text{Au}$ , and  $^{198}\text{Au}$  were obtained based on calculations performed using the JENDL-4.0 data library.<sup>74</sup> Using equation 9, the flux for both isotopes was determined in run 1 using the areal density of Au foil irradiated, the time of irradiation, the activity at time zero (determined previously using the gamma spectra and Genie 2000 software), and decay constant for each isotope. The flux determined for  $^{196}\text{Au}$  and  $^{198}\text{Au}$  was used to solve for the cross section of each activation product. Each calculated cross section was compared to literature value determined using the JENDL-4.0 or ENDF data libraries. This process was repeated for runs 2, 3, and 4.

### **4.4 Results and Discussion**

#### **4.3.1 Activity at Time Zero**

Specific activities were determined for each activation product at time zero after irradiation. The values for each activation product by run are shown below in tables 8, 9, 10, and 11.

Table 8: Measured activation products for run 1

Target Activation Element	Activation Product	Activity at Time Zero (Bq/gram)	1 $\sigma$
Au	Au-196	4.06E+03	9.38E+01
	Au-198	1.58E+06	3.43E+04
Ir	Os-191	4.06E+02	1.62E+01
	Ir-192	2.17E+03	4.07E+01
	Ir-194	1.97E+05	3.93E+03

#### 4.4.2 Flux Determination

No information regarding the flux or cross section was provided for each run performed at Flattop. To solve for the cross section of each activation product, the flux would need to be determined for each run. A target of  $^{nat}\text{Au}$  foil has been shown previously to be used to determine the fission fractions from tests performed.<sup>12</sup> In all runs, the Au foil was positioned in the center of Flattop likely to be used for this purpose. Using this assumption, a neutron flux was calculated for  $^{196}\text{Au}$  and  $^{198}\text{Au}$  to be used for determine cross sections for activation products produced in each run. The parameters used to determine a flux for each run are shown below in tables 12, and 13.

Table 12: Parameters used to determine the Au-196 flux for all runs

Parameter	Run 1	1 $\sigma$	Run 2	1 $\sigma$	Run 3	1 $\sigma$	Run 4	1 $\sigma$
Fission Spectrum Ave. (cm <sup>2</sup> /1 atom)	3.91E-27 <sup>75</sup>	N/A	3.91E-27 <sup>75</sup>	N/A	3.91E-27 <sup>75</sup>	N/A	3.91E-27 <sup>75</sup>	N/A
Target Density (atoms/cm <sup>2</sup> )	1.48E+22	N/A	1.18E+22	N/A	1.18E+22	N/A	9.33E+21	N/A
Irradiation Time (sec)	7.20E+03	N/A	4.84E+03	N/A	6.72E+03	N/A	7.20E+03	N/A

Flux (neutrons/sec)	2.30E+09	5.33E+07	2.95E+08	8.14E+06	1.45E+07	9.57E+04	3.54E+06	5.63E+04

Table 13: Parameters used to determine the Au-198 flux for all runs

Parameter	Run 1	1 $\sigma$	Run 2	1 $\sigma$	Run 3	1 $\sigma$	Run 4	1 $\sigma$
Fission Spectrum Ave. (cm <sup>2</sup> /1 atom)	9.13E-31 <sup>75</sup>	N/A	9.13E-31 <sup>75</sup>	N/A	9.13E-31 <sup>75</sup>	N/A	9.13E-31 <sup>75</sup>	N/A
Target Density (atoms/cm <sup>2</sup> )	1.48E+22	N/A	1.18E+22	N/A	1.18E+22	N/A	9.33E+21	N/A
Irradiation Time (sec)	7.20E+03	N/A	4.84E+03	N/A	6.72E+03	N/A	7.20E+03	N/A
$\lambda$ Decay Constants (1/s)	2.98E-06 <sup>73</sup>	N/A	2.98E-06 <sup>73</sup>	N/A	2.98E-06 <sup>73</sup>	N/A	2.98E-06 <sup>73</sup>	N/A
Isotope Activity at Time Zero (Bq)	4.84E+05	2.15E+04	4.11E+04	1.83E+03	2.59E+03	1.15E+02	2.84E+02	1.27E+01
Flux (neutrons/sec)	5.82E+09	2.59E+08	5.82E+09	2.59E+08	5.82E+09	2.59E+08	5.82E+09	2.59E+08

The fission spectrum average cross section listed was taken from literature based on the JENDL-4.0 data library. The target density used for each run was calculated using the mass of each foil and density of the material. The length of irradiation times were consistent for each run. The isotope activity listed in Bq was determined using the properties of each foil listed in tables 4, 5, 6, and 7. Using equation 9, the parameters shown were used to solve for the Au-196 and Au-198 flux values by run. Note that in the case of a N/A, there was no uncertainty due to a constant, assumptions, or lack of information provided from Flattop runs. Additional details for this calculations are shown in appendix section A.1.1.

A comparison of the flux values determined above are shown below in table 14.

Table 14: Comparison of fluxes determined for Au-196 and Au-198 in each run

Run #	Au-196 Flux (neutrons/second)	1 $\sigma$	Au-198 Flux (neutrons/second)	1 $\sigma$	198/196	1 $\sigma$
1	2.30E+09	5.33E+07	2.00E+10	4.33E+08	8.67	0.33
2	2.95E+08	8.14E+06	3.17E+09	6.75E+07	10.74	0.44
3	3.82E+07	7.26E+05	1.11E+09	2.42E+07	29.19	1.05
4	3.54E+06	5.63E+04	1.86E+07	3.54E+05	5.27	0.16

The neutron flux calculated in each run for both isotopes produced shows a decreasing trend over time. This should not be the case as an order of magnitude decrease every few months would mean that the critical assembly would need to be replaced every few years when it has been used for at least a few decades. The uncertainties determined for each flux were less than 10%. The flux determined for Au-198 is ~one order of magnitude larger for each run than Au-196 due to an over assumption through use of the fission spectrum average cross section. Although both cross sections used are within the millibarns range, Au-198 production through the n-2n reaction

has an energy threshold of 8.1 MeV that prevents neutrons below that energy from being captured. Au-198 has a much lower energy threshold and has a thermal n-capture cross section in barns causing greater production as neutron energies decrease. The ratio comparing 198/196 ideally should be consistent between runs. However, due to assumptions made and lack of information provided variation up to a factor of 3 was seen.

#### 4.4.3 Cross Section Determination

Cross sections values were determined for each isotope produced through the n-p, n-2n, n- $\gamma$ , or n- $\alpha$  reaction. These values were determined using both flux values in each run. A comparison of each calculated cross section by run to literature values is shown below in tables 15 through 18. Note that all literature values were obtained using the JENDL-4.0 library except for Ir and Pt which was obtained using the ENDF/B-VII.1 library.

Table 15: Comparison of calculated cross sections for each activation product in run 1

Target Activation Element	Activation Product	Nuclear Reaction	Lit. Fission Spectrum Ave. (barns)	Au-196		Au-198	
				Calc. Cross Section (barns)	Ratio (Calc./Lit.)	Calc. Cross Section (barns)	Ratio (Calc./Lit.)
Au	Au-196	n-2n	3.91E-03 <sup>75</sup>	-	-	-	-
	Au-198	n- $\gamma$	7.71E-02 <sup>75</sup>	-	-	-	-
Ir	Os-191	n-p	8.92E-06 <sup>76</sup>	1.08E-03	121.12	1.25E-04	13.97
	Ir-192	n- $\gamma$	1.85E-01 <sup>76</sup>	2.77E-02	0.15	3.20E-03	0.02
	Ir-194	n- $\gamma$	9.15E-02 <sup>76</sup>	2.86E-02	0.31	3.30E-03	0.04
Pt	Os-191	n- $\alpha$	3.31E-07 <sup>76</sup>	2.56E-02	77336.41	2.95E-03	8917.80
	Pt-195m	n- $\gamma$	4.79E-02 <sup>76</sup>	5.64E-02	1.18	6.50E-03	0.14
	Pt-197	n- $\gamma$	4.07E-02 <sup>76</sup>	3.20E-02	0.79	3.69E-03	0.09
Ti	Sc-46	n-p	2.66E-03 <sup>75</sup>	3.35E-03	1.26	3.86E-04	0.15
	Sc-47	n-p	2.66E-03 <sup>75</sup>	9.55E-03	3.60	1.10E-03	0.41
	Sc-48	n-p	2.66E-03 <sup>75</sup>	6.00E-04	0.23	6.92E-05	0.03

In run 1, the calculated cross sections determined were within two orders of magnitude to the literature determined fission spectrum average from the ENDF or JENDL library. The exception was for Os-191 which showed a three order of magnitude difference when produced by the n-p reaction of Ir and a five order of magnitude deviation through the n- $\alpha$  reaction of Pt when comparing to Au-196 values. The cross section comparison to Au-198 values was one order of magnitude less than either Au-196 values. The discrepancy seen for Os-191 does not occur for other activation products in either foil. It is possible Os-191 has a larger cross section for lower energy neutrons or an energy threshold which was previous shown. Use of the fission spectrum cross sections assumes that an flux distribution is occurring while in each experimental run fluctuations occur through scattering and attenuation. Neutron flux information for this run is need to potentially correct for this anomaly.

Table 16: Comparison of calculated cross sections for each activation product in run 2

Target Activation Element	Activation Product	Nuclear Reaction	Lit. Fission Spectrum Ave. (barns)	Au-196		Au-198	
				Calc. Cross Section (barns)	Ratio (Calc./Lit.)	Calc. Cross Section (barns)	Ratio (Calc./Lit.)
Au	Au-196	n-2n	3.91E-03 <sup>75</sup>	-	-	-	-
	Au-198	n- $\gamma$	7.71E-02 <sup>75</sup>	-	-	-	-
Fe	Mn-54	n-p	5.76E-03 <sup>75</sup>	3.84E-02	6.67	3.58E-03	0.62
	Fe-59	n- $\gamma$	3.50E-03 <sup>75</sup>	1.63E-04	0.05	1.52E-05	0.00

	Sc-47	n-p	2.66E-03 <sup>75</sup>	9.10E-03	3.43	8.48E-04	0.32
	Sc-48	n-p	2.66E-03 <sup>75</sup>	7.08E-04	0.27	6.60E-05	0.02

In run 2, the calculated cross sections to literature cross sections were within two orders of magnitude for all activation products. The calculated values for Au-196 were about one order of magnitude larger than each cross section ratio determined for Au-198.

Table 17: Comparison of calculated cross sections for each activation product in run 3

Target Activation Element	Activation Product	Nuclear Reaction	Lit. Fission Spectrum Ave. (barns)	Au-196		Au-198	
				Calc. Cross Section (barns)	Ratio (Calc./Lit.)	Calc. Cross Section (barns)	Ratio (Calc./Lit.)
Au	Au-196	n-2n	3.91E-03 <sup>75</sup>	-	-	-	-
	Au-198	n- $\gamma$	7.71E-02 <sup>75</sup>	-	-	-	-
Ir	Ir-190	n-2n	6.42E-03 <sup>76</sup>	1.85E-04	20.76	6.35E-06	0.71

	Sc-47	n-p	2.66E-03 <sup>75</sup>	7.22E-02	27.21	2.48E-03	0.93
	Sc-48	n-p	2.66E-03 <sup>75</sup>	5.21E-03	1.96	1.79E-04	0.07

In run 3, the calculated cross sections determined were within two orders of magnitude to the literature values using either flux value except for Os-191. This run repeated the same target materials used in run 1 showing similar deviation for each activation product. The discrepancy in the Os-191 ratio was again larger for production through the n- $\alpha$  reaction of Pt opposed to the n-p reaction using Ir. The ratio values for Au-196 were one order of magnitude larger relative to Au-198 in both cases similar to run 1.

Table 18: Comparison of calculated cross sections for each activation product in run 4

Target Activation Element	Activation Product	Nuclear Reaction	Lit. Fission Spectrum Ave. (barns)	Au-196		Au-198	
				Calc. Cross Section (barns)	Ratio (Calc./Lit.)	Calc. Cross Section (barns)	Ratio (Calc./Lit.)
Au	Au-196	n-2n	3.91E-03 <sup>75</sup>	-	-	-	-
	Au-198	n-γ	7.71E-02 <sup>75</sup>	-	-	-	-
Co	Co-58	n-2n	1.69E-04 <sup>75</sup>	1.34E-02	79.01	2.54E-03	14.99
	Fe-59	n-p	1.48E-03 <sup>75</sup>	6.71E-02	45.24	1.27E-02	8.58
	Co-60	n-γ	5.58E-05 <sup>75</sup>	7.33E-01	13143.21	1.39E-01	2493.96
Cr	Pb-203	n-2n	5.18E-03 <sup>75</sup>	5.03E-02	9.71	9.54E-03	1.84
Pb	Cr-51	n-2n	1.45E-04 <sup>75</sup>	4.15E-04	2.87	7.88E-05	0.54
W	W-187	n-γ	4.76E-02 <sup>75</sup>	3.27E-01	6.86	6.20E-02	1.30

In run 4, the calculated cross sections determined using either flux were within two orders of magnitude relative to the literature values. The only exception was Co-60 produced through the n-γ reaction of Co with a three order of magnitude increase relative to other isotopes produced from Co. This is similar to what was seen with Os-191 and is likely caused by a sensitivity to lower energy neutrons or energy threshold which was not accounted for when using the ideal fission spectrum average.

#### 4.5 Conclusion

Calculated cross sections in each run showed a ~two order of magnitude difference when comparing to literature values. This was seen in Au-196 which consistently had a 1 to 2 order of magnitude larger cross section while Au-198 generally had a 1-2 order of magnitude smaller cross section. The variation seen between the two fluxes was due to the energy reaction threshold for Au-196 decreasing the total flux determined while Au-198 had a slightly higher flux based on a sensitivity to thermal neutrons. The only discrepancies seen were in the production of Os-191 from natural Ir or Pt or Co-60 produced from natural Co. In both fluxes, the ratio of cross sections determined was off by at least three orders of magnitude likely due to use of the fission spectrum

average cross sections from literature. The fission spectrum cross section used was based on an ideal neutron spectra which did not take correct for attenuation and neutron scattering caused by the surrounding environment outside of the fission source. Improvement of these cross sections could be performed by using the actual neutron spectra for each run to adjust each cross section from literature. However, this information is not available to the public.

## **CHAPTER 5: BATCH CONTACT STUDIES OF SCANDIUM AND TITANIUM ON EXTRACTION CHROMATOGRAPHY RESINS FOR SEPARATION METHOD DEVELOPMENT**

### **5.1 Introduction**

In this chapter, batch contact studies were performed to determine the retention of stable scandium and titanium to different extraction chromatography resins. These studies are used to determine a separation factor based on differing retention of each analyte determined in different acid conditions. In chapter 4, it was shown that small quantities of  $^{46}\text{Sc}$ ,  $^{47}\text{Sc}$ , and  $^{48}\text{Sc}$  was produced from  $^{\text{nat}}\text{Ti}$  through the n-p reaction. In this work, strong acid systems will be employed to separate scandium and titanium based on their differing oxidation states in solution. Optimal parameters will be developed based on the extraction of trivalent scandium from tetravalent titanium. In chapter 6, the optimal conditions determined will be adapted to column separation studies.

Extraction chromatography resins Ln 1 and DGA normal (unbranched) produced from Eichrom technologies, described in section 2.3, have been shown previously to preferentially extract trivalent species such as lanthanides and actinides.<sup>35,36,77-79</sup> Batch contact studies based on the method outlined in chapter 3 will be performed in hydrochloric and nitric acid.

### **5.2 Materials**

All materials used in this chapter are listed in Section 3.1.

## **5.3 Experimental Procedure**

### **5.3.1 Stock Solution Preparation**

All stock solutions were prepared by adding a aliquot of ICP-MS grade analyte standard into a glass scintillation vials filled with concentrated nitric acid. Each vial was dried down on a hot plate (105-110 C) to produce a residue of analyte followed by the addition of concentrated nitric acid to redissolve the sample. This process was repeated twice more where the final solution was brought up in the desired concentration of hydrochloric or nitric acid used for the study. A 1000 ppm stock solution of Sc, Ti, and combination solution at each concentration was produced unless otherwise noted.

### **5.3.2 Ln 1 Resin**

#### **5.3.2.1 Batch Contact Studies**

The general procedure for batch studies is described in section 3.4.1. Single and dual analyte (interference) batch studies were performed in 0.1 to 8 M HCl and 0.1 to 11 M HNO<sub>3</sub>. A resin mass of  $50 \pm 2\%$  mg Ln 1 resin was weighed into a 2 mL microcentrifuge vial and preconditioned using 1 mL of acid. Vials were mixed for 1 hour and left upright overnight to allow the interstitial space between each resin bead to expand. Each vial was spiked with 0.5 mL of a matching acid solution containing of  $1000 \pm 1\%$  ppm Sc followed by 1 hour of mixing. This spike solution was produced prior to the experiment using the method outline in section 5.3.1. Each solution was transferred into a syringe connected to a PTFE tip and filtered into a clean 2 mL microcentrifuge vial. An aliquot from each vial was diluted and analyzed on an ELAN DRC II ICP-MS per the method described in section 3.6.2.2. Four replicates were performed for each

acid concentration. This method was repeated using  $1000 \pm 1\%$  ppm Ti, and a combination of  $1000 \pm 1\%$  ppm Ti and Sc.

### **5.3.2.2 Data Analysis**

The weight distribution  $D_w$  followed by conversion to  $k'$  was using equation 8 described in section 3.4.1.2 with the physical constants for Ln 1 resin shown below in table 19.

### **5.3.3 DGA Normal Resin**

#### **5.3.3.1 Batch Contact Studies**

The general procedure for batch studies is described in section 3.4.1. Single and dual analyte (interference) batch studies were performed using in 0.01 to 8 M HCl and 0.01 to 10.5 M HNO<sub>3</sub>. Three variations of the batch contact studies were performed using DGA (normal) resin. All stock solutions were prepared previously using the method outline in section 5.3.1.

In variation 1 (the UNLV method), the Ln 1 resin procedure in section 5.3.1.1 was duplicated using DGA normal resin. In this method, analysis was performed using an Optima 8000 ICP-AES described in section 3.6.1.2.

In variation 2 (the CSU method), the Ln resin procedure in section 5.3.1.1 was duplicated using DGA resin at analyte concentrations of  $750 \pm 1\%$  ppb for single and dual analyte studies. In this method, analysis was performed using a NexION 350 ICP-MS described in section 3.6.2.2. Solutions were produced by diluting ICP-MS grade Sc and Ti stock solutions due to issues with Ti precipitation during the dry down process described in section 5.3.1. A lower analyte concentration was used due to a reduced upper limit of detection for the ICP-MS opposed to the ICP-OES. This method was performed in an attempt to replicate the UNLV data using equipment available at CSU.

In variation 3 (LANL method), a single analyte batch study was performed using Sc in HCl and HNO<sub>3</sub>. Stock solutions were prepared using ACS grade Sc<sub>2</sub>O<sub>3</sub> using the method outline in 5.3.1.

A  $50 \pm 2\%$  mg sample of resin was weighed into a 1.2 mL Bio-Spin® chromatography column followed by preconditioned using 0.9 mL of acid. Vials were capped followed by mixing for 1 hour and left upright overnight to swell. Each column was spiked with a 0.3 mL matching acid solution containing ~1000 ppm Sc followed by 1 hour of mixing. Each columns tip was removed and solutions were drained into glass scintillation vials. Three replicates were performed for each acid concentration. At each acid concentration, two additional samples with different compositions were prepared. The first sample followed the procedure above but used 1.2 mL of clean acid in resin without the addition of the Sc spike. The second sample used 0.9 mL of clean acid and 0.3 mL of Sc spike without any resin. An aliquot of each sample diluted and analyzed using the ICAP 6500 DUO ICP-AES described in section 3.6.1.2. This method was performed to replicate previous work performed at LANL in an attempt to determine discrepancies between batch study results.

### **5.3.3.2 Data Analysis**

The weight distribution  $D_w$  followed by conversion to  $k'$  was calculated using equation 8 per section 3.4.1.2 using the physical constants for DGA resin shown below in table 19. Volume corrections for DGA resin in each acid were determined based on the volumes used in the UNLV batch study. Description of the method is shown in section 3.4.3 and the values are listed below in table 20. These were used to correct for the volume lost in each UNLV and CSU study as the method is based on using microcentrifuge vials followed by filtration.

Table 19: Physical constants of slurry-packed columns

Physical Properties	HDEHP <sup>33</sup>	TODGA <sup>34</sup>
Extractant Density (g/mL)	0.96	0.88
Bed Density (g/mL)	0.38	0.38
Resin Density (g/mL)	1.15	1.13
$V_s$ (mL)	0.16	0.17
$V_m$ (mL)	0.67	0.66
$V_s/V_m$	0.24	0.26
$D_v$ Conversion Factor (C1)	0.239	2.2
$K'$ Conversion Factor (C2)	0.57	0.57
Capacity (mg Eu/g resin)	50	10.6

Table 20: DGA resin volume corrections

	HCl Volume Lost (%)	1 $\sigma$	HNO <sub>3</sub> Volume Lost (%)	1 $\sigma$
0.1 M	7.63	0.02	8.45	0.06
1 M	7.97	0.01	8.69	0.02
10 M	8.57	0.03	8.77	0.04

### 5.3.3.3 Kinetic Batch Contact Study

The UNLV single analyte study method was replicated using a mixing time of 2.5 hours instead of 1 hour after addition of the spike solution. This was performed in hydrochloric acid using Sc and Ti. Three replicated were performed at each acid concentration.

### 5.3.3.4 Data Analysis

The data was analyzed in the same manner as the previous batch contact studies described in section 5.3.2.2.

## 5.4 Results and Discussion

### 5.4.1 Ln 1 Resin

The results for single analyte batch contact studies of scandium and titanium using Ln 1 resin in a nitric acid system in figures 13 and in a hydrochloric acid system in figure 14.

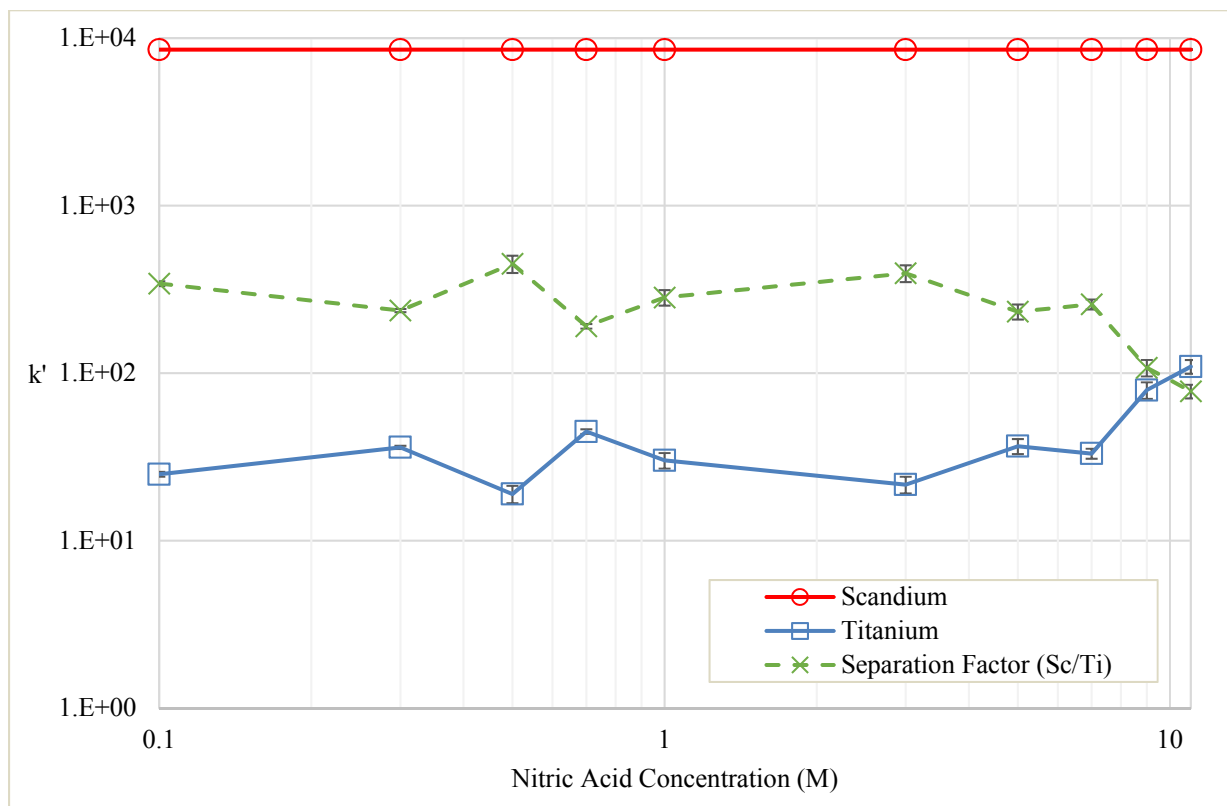

Figure 13: Single analyte batch contact studies using Ln 1 resin in nitric acid

In nitric acid, the scandium concentration measured was below the detection limit from 0.01 to 11 M nitric acid. This is likely due to Sc predominantly forming  $\text{Sc}(\text{NO}_3)^{38}$  in solution allowing the HDEHP ligands on the Ln 1 resin to compete for coordination of the metal pushing each nitrate group off. The value for the detection limit of 0.01 ppb ( $k'$  of 8500) was substituted

for purposes of determining a separation factor. A  $k'$  of  $\sim 30$  for titanium was determined from 0.1 to 6 M which is equivalent  $\sim 60\%$  sorption to the resin. The retention of Ti seen is likely due to formation of  $\text{Ti}(\text{NO}_3)_4$  which will similarly extract by HDEHP coordinating to the metal center and pushing the three of the nitrate off. The lower overall extraction may be due to a mixture of the  $\text{Ti}(\text{NO}_3)_4$ , and  $\text{TiO}_2$  species. It is possible that the lower extraction is due to the inability of the ligand to bind to  $\text{TiO}_2$  causing the lower overall retention. From 6 M to 11 M, a slight increase in retention occurred up to a  $k'$  of  $\sim 110$  or 85% sorption which is likely caused by an increase in  $\text{Ti}(\text{NO}_3)_4$  species. The separation factor fluctuated around  $\sim 300$  until 6 M followed by a slight decrease to  $\sim 80$  at 11 M.

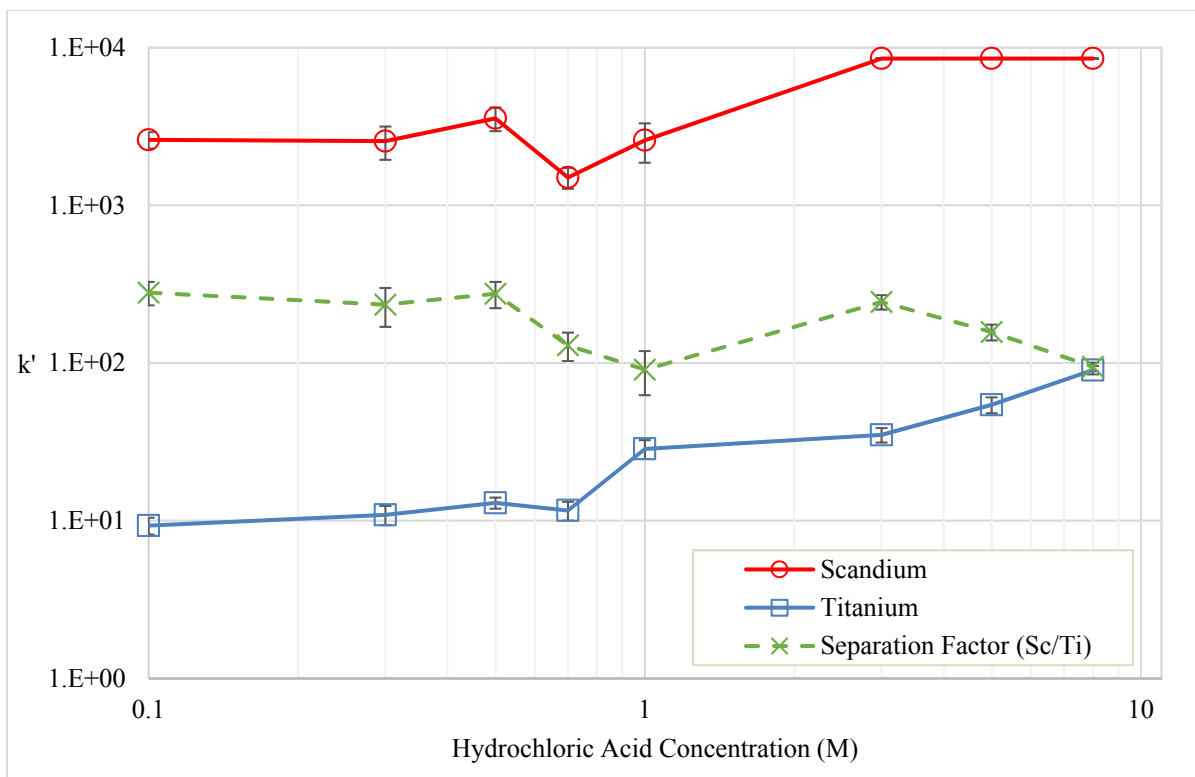

Figure 14: Single analyte batch contact studies using Ln resin in hydrochloric acid

In hydrochloric acid, the retention of Sc and Ti was consistent compared to previous nitric acid batch studies. Scandium was highly retained over the entire range from a  $k'$  of ~2600 up to 8500 which is equivalent to greater than 99% sorption. The increase in retention is likely due to a rise in chloride anions complexing to form  $\text{ScCl}_3$ .<sup>38,40</sup> Similar to the nitric system, HDEHP ligands in the Ln resin likely coordinated to the metal center pushing off chloride species so as to extract the neutral Sc into the stationary phase. The value for the detection limit of 0.01 ppb ( $k'$  of 8500) was substituted for 2, 4, and 8 M hydrochloric acid as the scandium concentration measured was below the detection limit. Similarly, Ti retention slowly increased with a  $k'$  of ~10 at 0.1 M up to 90 at 8 M likely due a slight complexation with chloride anions to form a mixture of  $\text{TiO}_2$ , and  $\text{TiCl}_{2-4}$ .<sup>41</sup> It is likely that titanium chloride species became predominant after 5 M when the retention surpassed 50. The separation factor gradually decreased from ~280 at 3 M to ~100 at 8 M as Sc retention did not change while Ti retention increased.

In both studies, scandium was retained at or above ~99% to Ln 1 resin. Titanium was retained from ~35 to 85% in hydrochloric and ~60 to 85% in nitric acid which is high for a separation. Overall, the retention of scandium was good but the even at titanium lowest retention point (0.1 M HCl) ~35% was retained giving an overall separation factor of ~300. This might be a reasonable separation factor if the intended solution contained a 1 to 1 ratio of scandium to titanium but based on the few measurements of scandium produced by the n-p reaction of titanium in chapter 4, less than 1% of the target converted to scandium.

## 5.4.2 DGA Resin

### 5.4.2.1 Single Analyte Batch Studies

The results for the UNLV variant single analyte batch contact studies using DGA resin in nitric acid are shown in figure 15, and in hydrochloric acid in figure 16 below.

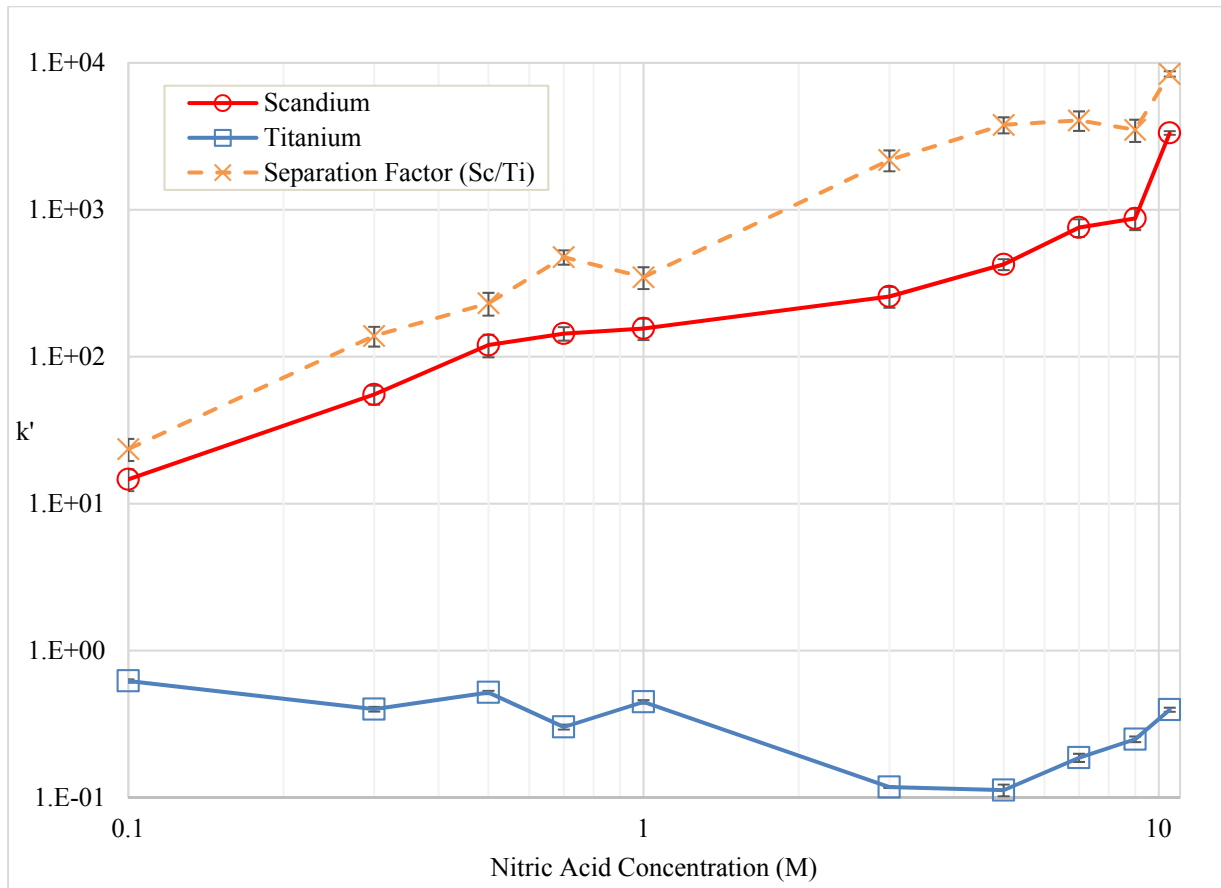

Figure 15: UNLV single analyte batch contact study DGA resin in nitric acid

Each element was contacted separately to determine the sorption potential on DGA resin in nitric acid. Scandium retention increased ~24 to ~350 or in terms of percent sorption from ~45 to ~90% as the nitric acid concentration increased from 0.1 to 1 M. Similar to previous nitric acid

work in Ln resin, Sc retention increased with anion concentration forming  $\text{Sc}(\text{NO}_3)$  which was extracted by DGA coordinating to the metal center. The retention of titanium remained below 1 across the entire range varying in sorption from  $\sim 0.7$  to 3.5%. The lower trend seen in Ti is likely due to the mechanism of extraction. In Ln resin, the ligand is unidentate while in DGA the ligand bidentate likely making it more difficult to coordinate to Ti due to steric hindrance. This may also account for the slightly lower retention of Sc to DGA resin across the entire range relative to the Ln resin study. The separation factor of scandium to titanium increased from  $\sim 20$  to 2000 by 3 M finally reaching  $\sim 8400$  at 10.5 M.

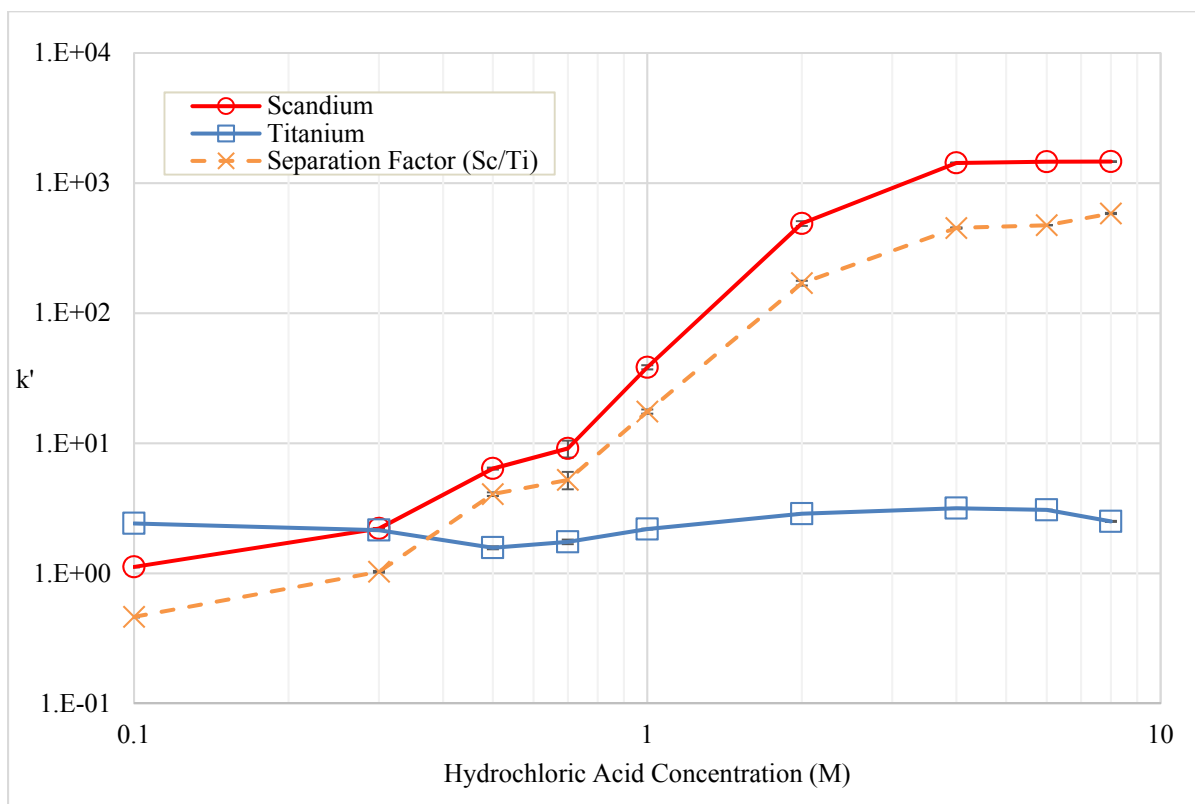

Figure 16: UNLV single analyte batch contact study using DGA resin in hydrochloric acid

Each element was contacted separately to determine the sorption potential on DGA resin in hydrochloric acid. Similar to the Ln resin studies, Sc retention increased with a rise in chloride anion concentration. The significant change in retention from low to high acid is likely due to the inability of the ligand to extract  $\text{Sc}(\text{OH})_3$  while able to extract the  $\text{ScCl}_3$  which slowly became the dominant species as the chloride concentration increased. This is shown through Sc retention increasing from  $\sim 1$  to  $\sim 1400$  or a percent sorption of  $\sim 6$  to  $\sim 99\%$  from 0.1 to 4 M. As in the case of nitric acid studies, titanium retention remained low and stagnant due to inability of the DGA ligand to extract Ti in either the oxide or nitrate form.

Overall, Ti retention was higher in hydrochloric acid for the DGA studies fluctuating around a  $k'$  of  $\sim 2$  to 3 with a percent sorption varying from  $\sim 8$  to 16% over the range. The separation factor of Sc to Ti increased from  $\sim 0.5$  at 0.1 M up to a maximum of 583.41 at 8 M. However, this was lower than separation factors determined in nitric acid which ranged from  $\sim 8000$  to 25000 at high nitric acid concentration.

#### **5.4.2.2 Kinetic Batch Study**

The results for single analyte kinetic batch contact studies of scandium and titanium DGA resin shown below in figure 17.

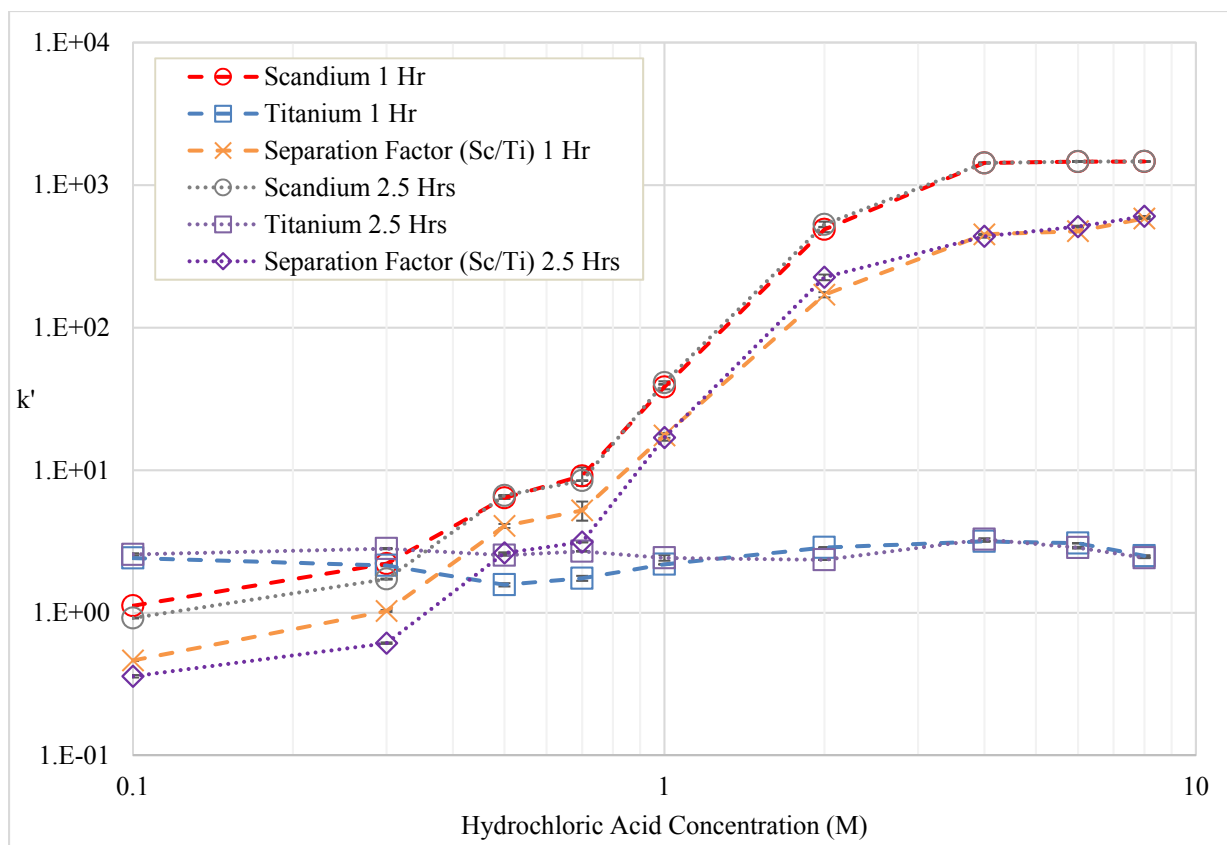

Figure 17: UNLV single analyte kinetic study using DGA resin in hydrochloric acid

A kinetic study was performed to confirm whether the batch study method had allowed sufficient time for extraction of scandium and titanium in hydrochloric acid. Each element was contacted separately to determine the sorption potential of DGA resin in hydrochloric acid at 2.5 hours to compared to previous batch study data. The difference between at each data point relative to the average retention at each acid concentration showed a variance of ~9% at 0.1 up to 0.3 M, decreasing to ~2.5% between 0.3 up to 1 M, finally decreasing to ~0.1% variation between 1 and 8 M hydrochloric acid. Little variation was seen between the two sets of data.

### 5.4.2.3 Dual Analyte Batch Studies

The results for the dual analyte batch contact studies otherwise known as interference studies using DGA resin in nitric acid are shown below in figure 18 and in hydrochloric acid in figure 19.

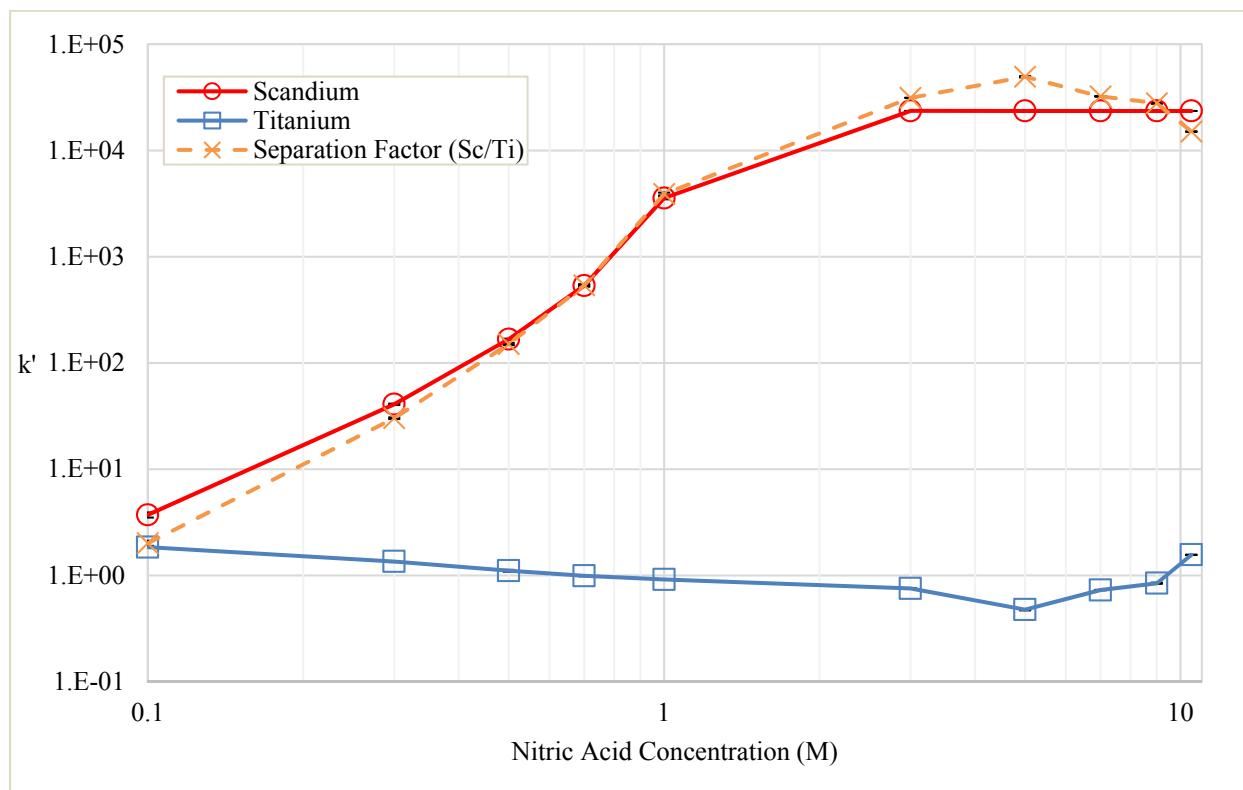

Figure 18: UNLV dual analyte batch contact study using DGA resin in nitric acid

Scandium and titanium were contacted simultaneously to determine any significant variation in sorption on DGA resin in nitric acid. Similar to the single analyte study, scandium showed an increasing  $k'$  of ~17 to ~4000 from 0.1 to 1 M. Scandium retention was shown to be significantly lower than the single analyte study below 0.3 M while increasing at a larger slope above 0.3 M. Scandium concentration from 3 to 10.5 M was below the detection limit so a value

was substituted based on the instruments LOD of 0.01 ppm giving a ~99% retention or  $k'$  of ~28,000.

Titanium retention remained stagnant around a  $k'$  of 1 with slight fluctuations likely due random processes such as sorption to the container walls. A slight decreasing trend was shown up to 5 M followed by a slight increase up to 10.5 M. The entire retention range shifted from 0.48 to 2.01 with 2.01 at 0.1 M down to 1.56 at 10.5 M.

Overall, titanium retention to the resin was slight larger but not very significant with a percent sorption range of ~3 to 10%. The separation factor of Sc to Ti showed an increasing trend due to the significant increase in Sc extraction as the nitrate concentration increased from ~2 at 0.1 M to ~15,000 at 10.5 M. Similar to the single analyte studies, a large separation factor of 8000 or more was seen at high nitric acid concentration.

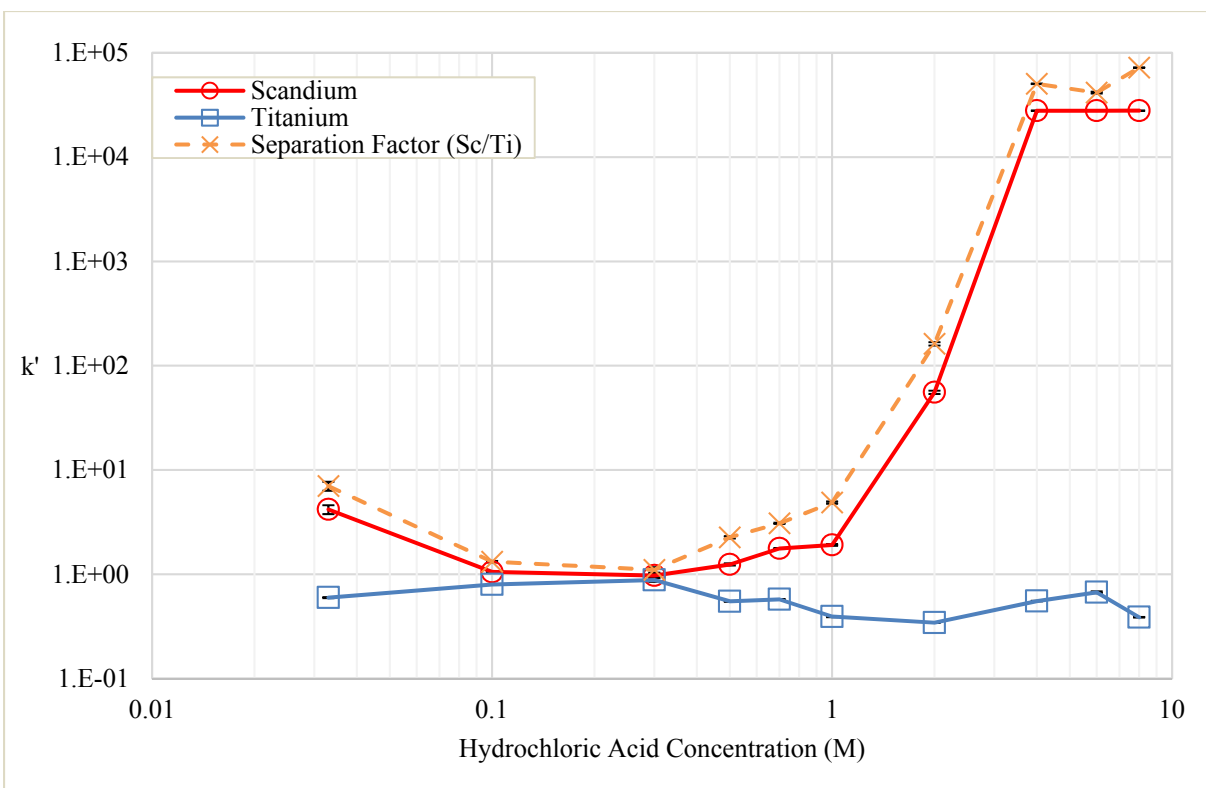

Figure 19: UNLV dual analyte batch contact study using DGA resin in hydrochloric acid

The UNLV interference method was employed to determine any significant variation in sorption of scandium and titanium to DGA resin in hydrochloric acid. Unlike the previous single analyte studies, the interference study was performed below 0.1 M which showed a decrease in retention from ~20% to 6% at 0.1 M. This slight decrease may be due to mechanisms such as retention to the wall of the container causing a slightly higher retention at 0.3 M HCl. Additional studies need to be performed to determine if this is a data processing, instrument or chemistry issue. From 0.1 to 4 M, there is a gradually increasing slope in scandium retention to a value below the LOD from 4 to 10 M. The value for the LOD of 0.01 ppm was substituted equivalent to ~99% retention or a  $k'$  of 28,000.

As in the other studies, titanium remained stagnant around ~1 likely due to the inability of the bidentate TODGA ligand to coordinate Ti. A slight titanium retention of ~2 to 4% was observed across the acid range which may be due to other processes occurring such as adsorption to the container walls or inert resin support. The separation factor of Sc to Ti increased from ~5 at 0.3 M up to ~70,000 at 8 M. Note again that the separation factor was significantly higher due to use of the LOD value for the instrument used.

#### **5.4.2.4 Comparison of Scandium Retention Studies**

A comparison between published studies and batch studies performed for this dissertation are shown below in hydrochloric and nitric acid. Comparison plots of these studies to the UNLV single batch studies are shown in figures 20, and 21. Each set of data was converted from  $D_w$  to  $k'$  using the conversion factor shown in table 19 in attempt to compare different methods. The retention values determined from the UNLV single analyte, Roman, and Dirks studies were determined using a batch contact study method. The Alliot retention values were determined using a column study.

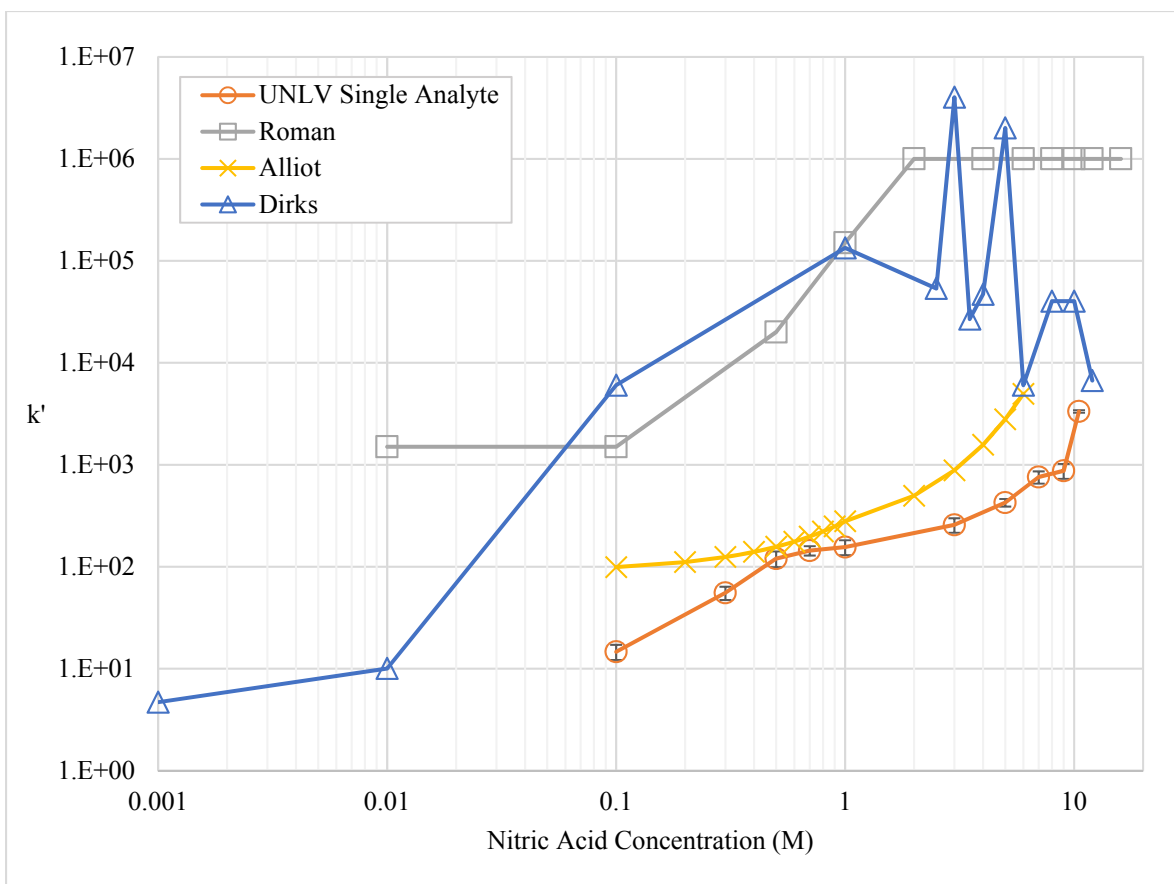

Figure 20: Comparison of multiple scandium retention studies using DGA resin in nitric acid. The Roman, Alliot, and Dirks data was extracted from published papers<sup>16,80,81</sup>

All of the data sets show an increasing trend of scandium retention in DGA resin as the nitric acid concentration increased. This was previously discussed to occur based on the increase in  $\text{Sc}(\text{NO}_3)_3$  species as the nitrate concentration increased. The work by Alliot and the UNLV single analyte study showed the closest similarity across the range with fairly close  $k'$  values from 0.1 to 6 M nitric acid. The difference between the Alliot and the UNLV values are under an order of magnitude varying from  $\sim 1.3$  to  $6.5$  while the Roman and Dirks data are consistently 2 to 3 orders of magnitude higher. The Dirks data show a low scandium retention at 0.01 M but swiftly

increases with a slope of  $\sim 2$  and a  $k'$  2.5 orders of magnitude higher relative to the UNLV data at 0.1 M. Similarly, the Roman data increases with a slope of  $\sim 2$  from 0.1 to 2 M.

Looking at the different methods, the UNLV, Dirks, and Roman methods were all very similar using ppm quantities of Sc in 50 mg of resin. The volume of acid for each varied from 1.2 to 1.5 mL with mixing times from 30 minutes to 1 hour. Analytes were measured using a ICP-AES for Roman and the UNLV data while a ICP-MS was used to analyze the Dirks data. The only significant difference between the three procedures was the filtration method. In the UNLV study, a PTFE filter and syringe was used while a 2 mL biospin column was drained in the Roman study, and a centrifuge was used to separate the two phases in the Dirks study. It is unclear as to why these methods should differ significantly as the Alliot method using column studies showed the closest retention values to the UNLV data across the acid range. It should be noted that the Alliot method used multiple analytes at unknown concentrations to achieve this distribution.

Based on the UNLV study, a scandium sorption of 99% is equivalent to a  $k'$  value of 1000 which is still below majority of Roman and Dirks data. Their data seems to continuously increase purely on their ability to detect signal. This is clearly shown at very high acid concentrations in the Dirks study where retention values fluctuated significantly while maintaining sorption above 99%.

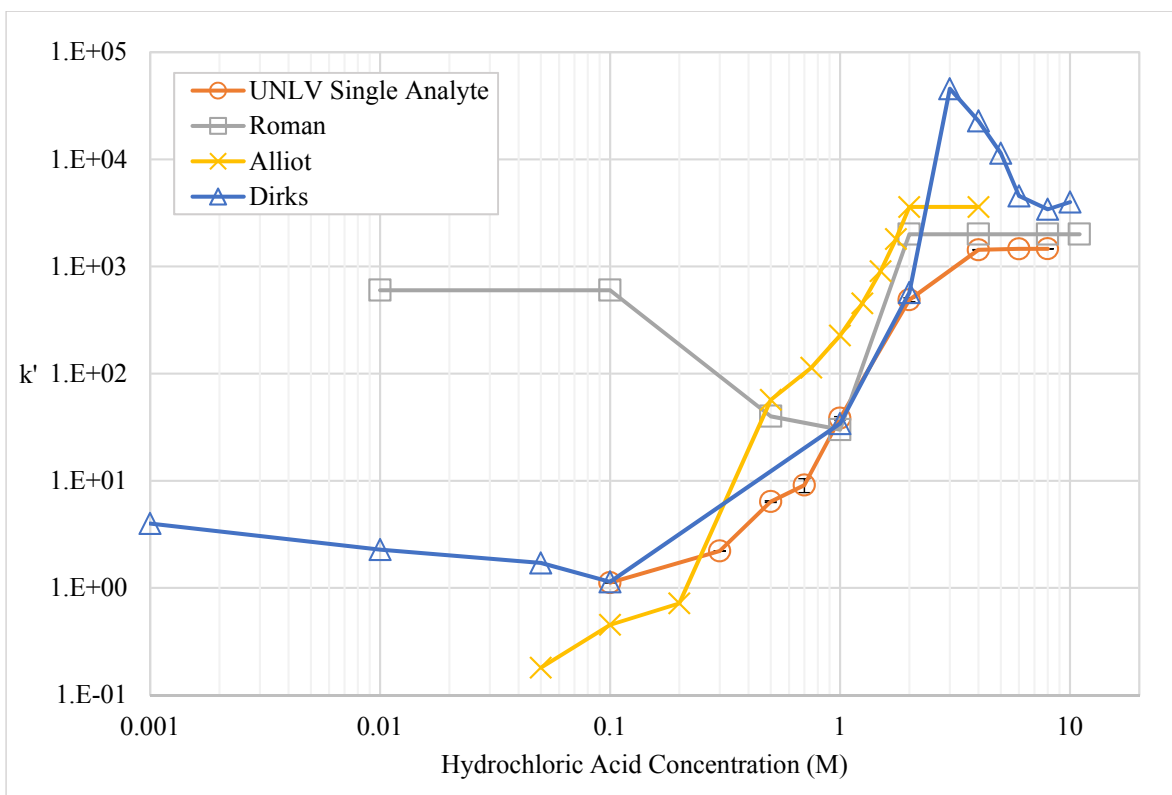

Figure 21: Comparison of multiple scandium retention studies using DGA resin in hydrochloric acid. The Roman, Alliot, and Dirks data was extracted from published papers<sup>16,80,81</sup>

All of the data sets show an increasing scandium retention trend from 1 to 10 M with minor variations at high acid in the Dirks data likely due to a lower limit of detection through measurement using a ICP-MS. This is likely due to increased formation of  $\text{ScCl}_3$  as the anion concentration increased. Similar to the nitric acid comparison, the Alliot data was similar to the UNLV study data in terms of slope with a slightly higher  $k'$  overall. In the Dirks data, a slight decrease in retention was shown from 0.001 to 0.1 M followed similar data to the Alliot and UNLV data from 0.1 to 10 M.

The Roman data showed significantly higher sorption across the entire acid range similar to the previous comparison in nitric acid. In hydrochloric acid, the data decreased by an order of magnitude from 0.1 to 1 M followed by an increase in  $k'$  retention similar to Dirks and the UNLV

study up to 2 M. The decrease shown for Dirks and Roman at low acid may be caused by a sorption to the container wall or additional mechanism not clearly explained in their procedures.

Although, there was some discrepancy in the retention values determined in each study, all of the different studies came to the same conclusion that 0.1 M hydrochloric acid would be optimal for stripping Sc from DGA resin. With large discrepancies in data, an attempt was made to replicate the results from the Dirks and Roman studies.

In the Roman study, batch contact studies were performed used biospins columns noted in the LANL method listed in 5.3.2.1 to measure single analyte Sc retention using ICP-AES. The Dirks method utilized batch studies using a low ppm concentration of Sc in 1.4 mL of acid followed by mixing for thirty minutes.<sup>81</sup> Dirks used the method of separating samples using a centrifuge which was hard to replicate as no experimental instructions were included. Samples from the Dirks study were analyzed using ICP-MS which could explain why the retention values were significantly higher due to a limit of detection. In this work, the CSU interference method was employed to replicate the Dirks data using a lower concentration of Sc and measured using a ICP-MS. No attempt was made to replicate the Alliot method as it involved multiple additional elements at concentrations not listed. Comparison plots of the UNLV single analyte, UNLV interference, CSU interference, and LANL biospin data sets are shown below in figures 22, and 23.

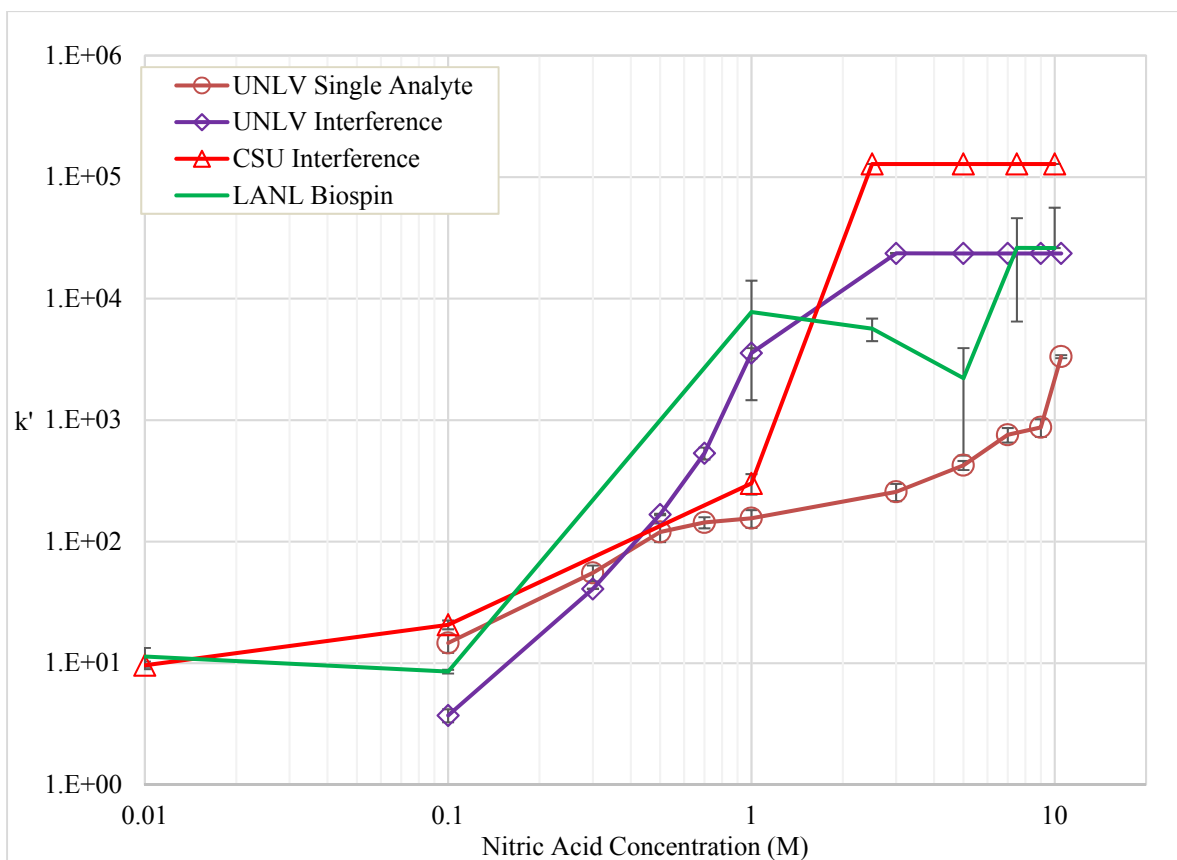

Figure 22: Comparison of UNLV, CSU, and LANL methods for scandium retention on DGA resin in nitric acid

Each set of data follows a similar trend of scandium retention increasing with acid concentration. The LANL and UNLV interference methods show a steeper increase in slope from 0.1 to 1 M reaching greater than ~90% sorption by ~0.5 M while the CSU interference and UNLV single analyte data reached ~90% sorption by 1 M. From 1 M onward, the CSU and UNLV interference studies reached their detection limits by ~3 M while the LANL data decreased slightly due to human error in performing manipulating the biospin columns. In each of the studies, the uncertainty between replicates at any acid concentration was under 20% while in the LANL study uncertainties up to 75% were determined at  $k'$  values at 1 M or higher. However, at these values the sorption was significantly higher than 99%. The UNLV single analyte study slowly increased

reaching full retention near 10.5 M. Although, there was some discrepancy in retention between the four runs, UNLV interference and LANL methods were consistently 1 order of magnitude lower from 1 M onward compared to the Dirks and Roman data in figure 20. Replication of the Roman method shown as LANL Biospin and the CSU interference method instead showed a confirmation of the UNLV studies at up to 1 M followed by variation in retention values representing sorption greater than 99% for all studies from 1 to 10 M nitric acid.

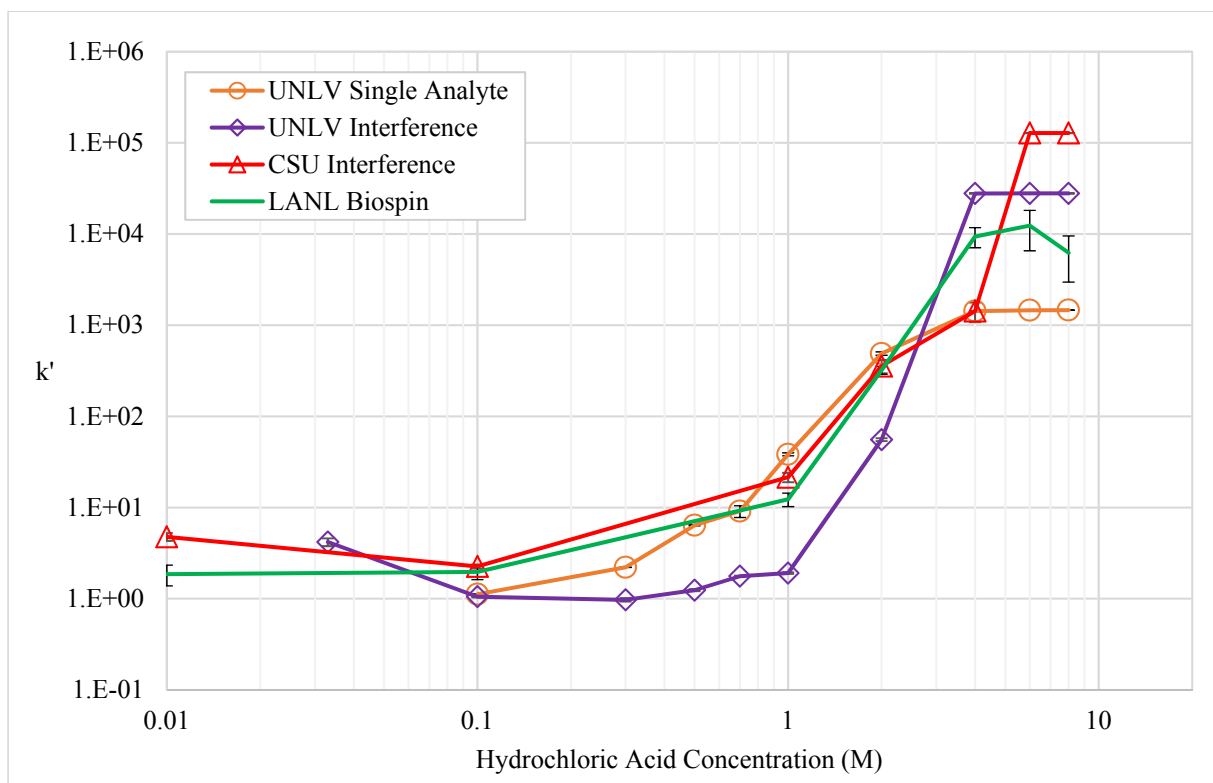

Figure 23: Comparison of UNLV, CSU, and LANL batch contact study methods for scandium using DGA resin in hydrochloric acid

Similar to the comparison in figure 22, each set of data shows a gradual increase in scandium sorption up to ~95% or a  $k' \sim 1400$  at 3 M. The slight variations between the UNLV

single analyte, LANL, and CSU interference studies are likely due to slight variations in experimental reproducibility, instrumental drift, and data processing.

The significant decrease in retention shown in UNLV interference study is a bit harder to determine as there is a sorption decrease of 15% from 0.03 to 0.1 M followed by a comparatively steeper slope up from 1 to 4 M. It is possible that the CSU and LANL data may match closer to the UNLV interference data if additional batch studies were performed between 0.1 and 1 M hydrochloric acid. Both of these methods show a similar rising slope compared to the UNLV studies below 1 M unlike the previous Roman data in figure 21. An additional replicate study using the UNLV interference procedure and analysis method should be performed in an attempt to deduce the deviation between data sets.

#### **5.4.2.5 Comparison of Titanium Retention Studies**

A comparison of titanium retention from the UNLV studies, CSU study, and previous work by Pourmand<sup>82</sup> are show below in figures 24, and 25.

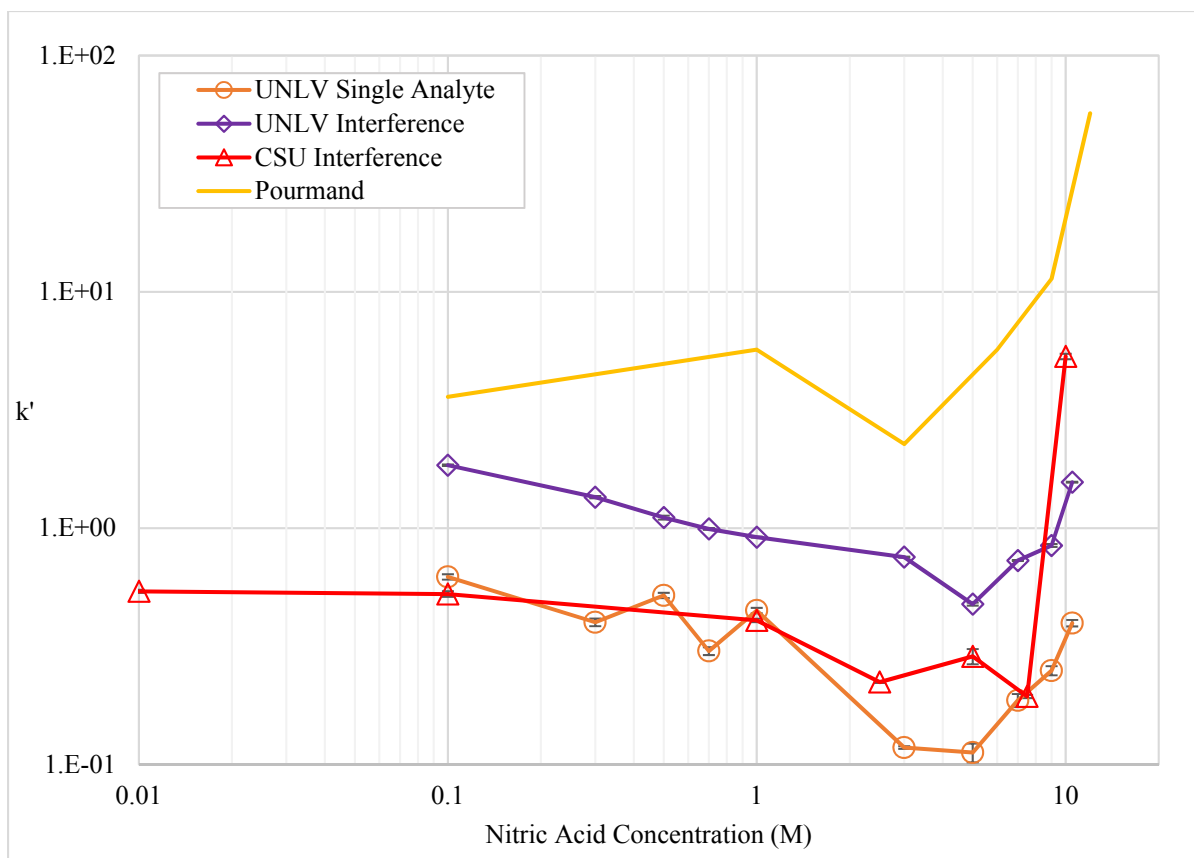

Figure 24: Comparison of multiple titanium retention studies using DGA resin in nitric acid. Pourmand's data was extrapolated from previously published work<sup>82</sup>

Each data set shows a decreasing retention of titanium from very low to ~5 M nitric acid and increase in retention from 5 M onward. The sorption of Ti in the UNLV and CSU studies from 0.01 to 9 M is under 10% or a  $k'$  of ~2 while the Pourmand data fluctuated slight higher at ~20 to 25% sorption. It is unclear why there is a slight decreasing trend in titanium sorption from 0.1 to 6 M in the UNLV and CSU studies followed by a rapid increase up to 10 M. The rapid increase shown at very high nitric acid may be explained by a speciation threshold where the dominant species in the solution is  $\text{Ti}(\text{NO}_3)_4$  allowing for small but significant increase in extraction by DGA resin. Additional batch contact studies up to 16 M nitric acid should be performed to determine if this increase is a fluke.

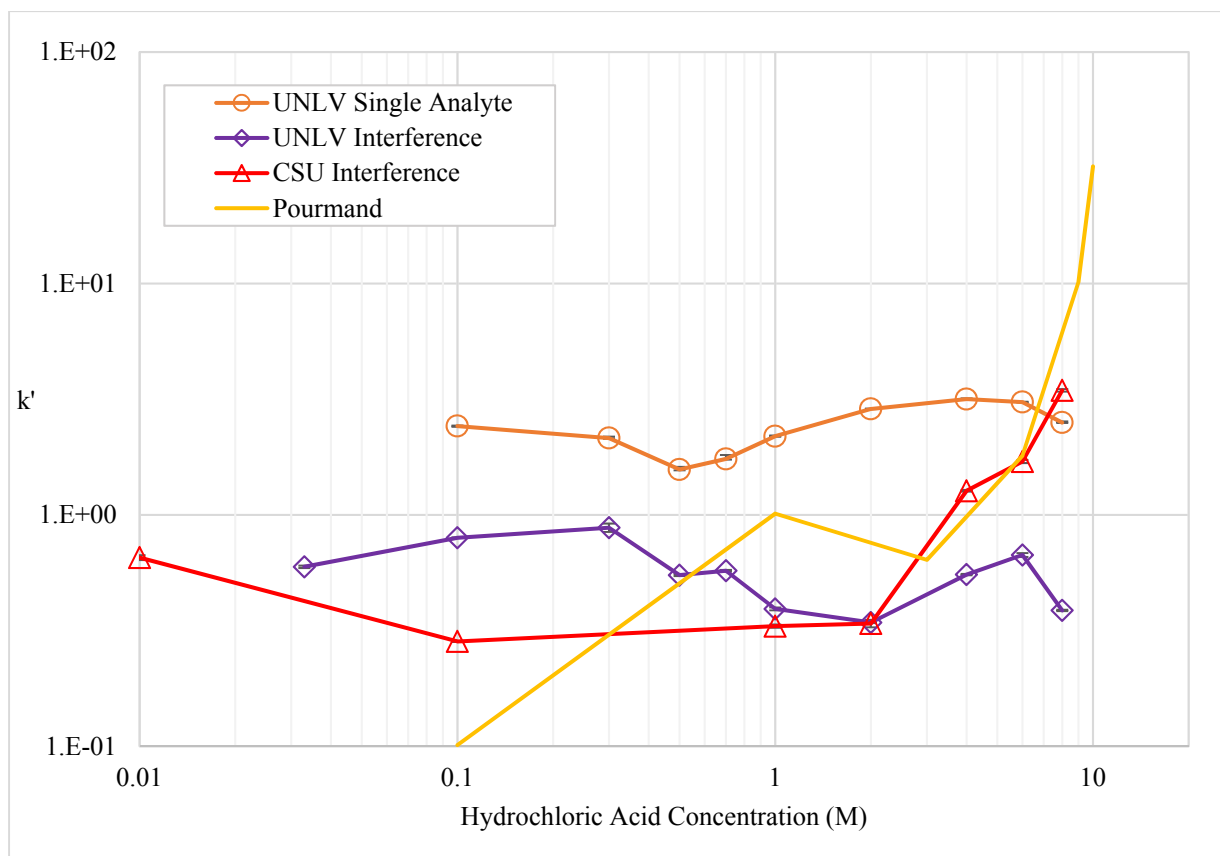

Figure 25: Comparison of multiple titanium retention studies using DGA resin from in hydrochloric acid. Pourmand's data was extrapolated from previously published work<sup>82</sup>

There does not seem to be an increasing or decreasing trend when comparing all of the UNLV and CSU studies up to 2 M hydrochloric acid. After 2 M, there is a fairly steep increase in retention for Pourmand and in the CSU interference data. The UNLV batch study and UNLV interference study stay fairly stagnant from 2 to 8 M. For each the UNLV and CSU studies, Ti is only sorbed from a few percent up to ~15% at any acid concentration. Similar to the nitric acid work, there does not seem to be much extraction by DGA resin across the acid concentration except by Pourmand at 10 M. However, replication of the Pourmand study wouldn't be possible as the number of analytes and concentrations used were not expressed for the batch studies. The only concentrations expressed were for the column elution studies performed.

## 5.5 Conclusions

The single analyte studies performed using Ln 1 resin showed a reasonable but not optimal separation method for Sc and Ti. In both acid systems, separation factors of ~100 to 300 were achievable but significant retention of titanium was seen in nitric and hydrochloric acid at ~60 and ~85%. The UNLV single analyte studies using DGA resin showed a Sc retention of ~1000 or higher as the acid concentration increased from 3 M in both acid systems. Although, the Sc retention decreased by one order of magnitude on average DGA resin, Ti retention decreased by at least two orders of magnitude with a retention around 1 in both acid systems at all concentrations. A slightly larger SF of ~600 was observed in hydrochloric acid while the SF factor in nitric acid at least ~8000 up to 25,000 at high acid concentration. The reason for this is likely due to the coordination mechanism of each resin ligand. Ln 1 resin uses a monodentate ligand that could coordinate to Ti allowing significant retention, while DGA resin used a bidentate ligand which did not seem to in acid solution. The reason for this is likely due to steric hindrance preventing extraction of Ti as a greater number of ligands would be required to extract a tetravalent species (Ti) opposed to a trivalent (Sc). The difference in Sc retention between the resins is likely due to the HDEHP ligand acting as a stronger electron donor than the TODGA ligand. The dual analyte studies replicated similar results to the single analyte studies. The kinetic study showed less than 10% difference in retention between 1 and 2.5 hour mixing time in hydrochloric acid. The difference in extraction is likely due to the coordination mechanism of each resin ligand.

Comparison of the different DGA methods by Dirks, Roman, Alliot and studies performed in this dissertation showed a general increase in Sc retention with acid concentration for both nitric and hydrochloric acid. However, in nitric acid, the Dirks and Roman data showed Sc retention values a few orders of magnitude greater across the acid range. Additionally, a decrease in Sc

retention was shown at very low (0.001 to 0.1 M) to 1 M hydrochloric acid in the Roman and Dirks data. Attempts to discern these issues by replicating the LANL method and repeating a slight adaption of the UNLV method (the CSU method) showed retention values closer to those determined from the UNLV single and dual analyte studies.

Based on the batch contact studies data, an optimal separation method was developed using a nitric acid system to sorb Sc to DGA resin while separating Ti. This could be followed by a stripping step using a low concentration of hydrochloric acid. Adaptation of this method to column studies using 5 M nitric acid and 0.1 M hydrochloric acid is shown in chapter 6.

## **CHAPTER 6: SEPARATION OF TITANIUM AND SCANDIUM USING DGA RESIN COLUMN STUDIES**

### **6.1 Introduction**

Using the separation parameters determined from batch contact studies in chapter 5, column studies were performed to separate scandium from titanium. In this chapter, column studies were performed using a wet slurry of DGA resin to determine the analyte distribution or elution profile of Sc and Ti in smaller quantities. This method will be scaled up in mass loading similar to the quantities used in chapter 4. If the gravity flow columns show a clean separation, then the method will be converted to vacuum column studies using prepacked resin cartridges at significantly faster flow rates. These faster flow rates through use of vacuum pressure is necessary to push the solution through a smaller interstitial space in these more tightly packed resin cartridges. In addition, these experiments at higher flow rates will be used to test if a high rate of extraction is still possible while significantly reducing the time needed for each extraction.

In these column studies, a significantly larger mass of resin will be used to ensure sufficient capacity while maintaining fast extraction kinetics. A 1:1 ratio of Sc to Ti is used initially for the elution profile proof of concept followed by substantial increased in Ti mass. A ratio of 1:100 Sc to Ti will be used in the later experiments with a two orders of magnitude mass loading increase up to 100 mg based on the mass of each Ti foil (~80-100 mg) used in the Flattop irradiation. Only 1 mg of Sc was used at the highest mass loading based on measurements of Ti foil showing less than 1% conversion to Sc.

### **6.2 Materials**

All materials used are for these column studies are described in section 3.1

## 6.3 Experimental Procedure

### 6.3.1 Gravity Column Studies

The general procedure for gravity column studies including FCV determination using a wet slurry of resin is described in 3.5.1. Two variations of the gravity column study using 500 mg DGA resin were performed based on the concentration of analyte separated. For three replicates using 500 mg of DGA resin,  $10 \pm 0.2$  drops of DI water was measured before 1 M hydrochloric acid eluted from the column. One FCV was determined to be equivalent to  $\sim 0.5$  mL. Each Eichrom cartridge used has a column volume of 2 mL.

In the first or elution profile study, a 5 mL load solution containing  $5 \pm 1\%$  mg Sc and  $10 \pm 1\%$  mg Ti in 5 M nitric acid was prepared from stock standards referenced in section 3.1. A mass of  $500 \pm 1\%$  mg of DGA resin was weighed in a 20 mL glass scintillation vial followed by the addition of  $\sim 1$ -2 M nitric acid. The resin solution was mixed on a shaker table for at least 2 hours to allow time for swelling. The resin was added to a 2 mL Eichrom chromatography column followed by the addition of glass wool. The column was conditioned using 5 FCVs of 5 M nitric acid (2.5 mL) and the number of drops per minute was measured to determine a flow rate. Acid was eluted until the solution level dropped to top of the resin bed. The 5 mL load solution was added in 1 mL intervals as the solution flowed down to the level of the resin bed. The column was washed with 5 FCVs of 5 M nitric acid (2.5 mL) to ensure complete Ti removal. A aliquot containing 5 FCVs of 6 M hydrochloric acid was then added to the column to convert the acid matrix without desorbing Sc. Finally, 15 FCVs of 0.1 M hydrochloric acid was added to strip Sc from the resin. Fraction were collected in 2 mL microcentrifuge every 2 minutes or  $\sim 1$  FCV.

In the second or elution fraction study, the method for preparing resin and the column remained the same while the mass of analyte, volumes of acid, and fraction collection method differed. In this method, a 15 mL load solution containing  $1 \pm 1\%$  mg Sc and  $100 \pm 1\%$  mg Ti in 5 M nitric acid was prepared from stock standards referenced in section 3.1. The column was conditioned using 5 FCVs of 5 M nitric acid prior to addition of the load solution. After the load solution was added, an additional 30 FCVs (15 mL) of 5 M nitric acid was used to wash the column any residual Ti. After the Ti elution step, the column was conditioned using 20 FCVs of 6 M hydrochloric acid (10 mL). Finally, the column was stripped of Sc using 60 FCVs of 0.1 M hydrochloric acid. Three separate fractions were collected instead of a fraction for every FCV. The first fraction or Ti elution step consisted of the 5 M nitric acid load and wash. The second fraction or column conversion step consisted of the 6 M hydrochloric acid elution. The third fraction or Sc stripping step consisted of the 0.1 M hydrochloric acid elution.

For each study, an aliquot from each fraction was diluted and analyzed using an Optima 8000 ICP-AES described in section 3.6.1.2. Each column study was replicated three times.

#### **6.3.1.1 Data Analysis**

The data analysis method used for the Optima 8000 ICP-AES is shown in section 3.5.1.2.

#### **6.3.2 Vacuum Column Studies**

The general procedure for the vacuum column studies including vacuum box set up is described in section 3.5.2.1. A vacuum box from Eichrom was set up using the associated pressure regulator, and tubing connected to a vacuum spout. A 15 mL load solution containing  $1 \pm 1\%$  mg Sc and  $100 \pm 1\%$  mg Ti in 5 M nitric acid was prepared from stock standards referenced in section 3.1. A 2 mL prepacked DGA resin cartridge was connected to a 20 mL syringe and attached to an

open spout on top of the vacuum box. The resin was wet by adding 10 mL of 5 M nitric to a syringe attached to the resin cartridge allowing the vacuum to pull the acid through the cartridge. The flow rate was measured at a rate of ~1 mL per minute. Next, the 15 mL stock solution was added to syringe followed by an additional 15 mL of clean 5 M nitric. The solution eluted off the column was collected in the Ti fraction vial. Next, 10 mL of 6 M hydrochloric was added to convert the resin prior to the Sc stripping step. The solution eluted off the column was collected in a separate fraction. Finally, 30 mL of 0.1 M hydrochloric acid was added to strip Sc and was collected in a separate fraction. This method was repeated at a flow rate of 3, and 5 mL per minute. For each study, an aliquot from each fraction was diluted and analyzed using an Optima 8000 ICP-AES per section 3.6.1.2. Each column study was replicated three times.

### **6.3.2 Data Analysis**

The data analysis method used for the Optima 8000 ICP-AES is shown in section 3.5.1.2.

## **6.4 Results and Discussion**

### **6.4.1 Gravity Column Studies**

The results for the 1:2 Sc to Ti gravity column study using wet slurry DGA resin is shown below in figure 26. The percent recovery of each analyte by elution phase is shown in table 21 while the decontamination factor for each phase is shown in table 22.

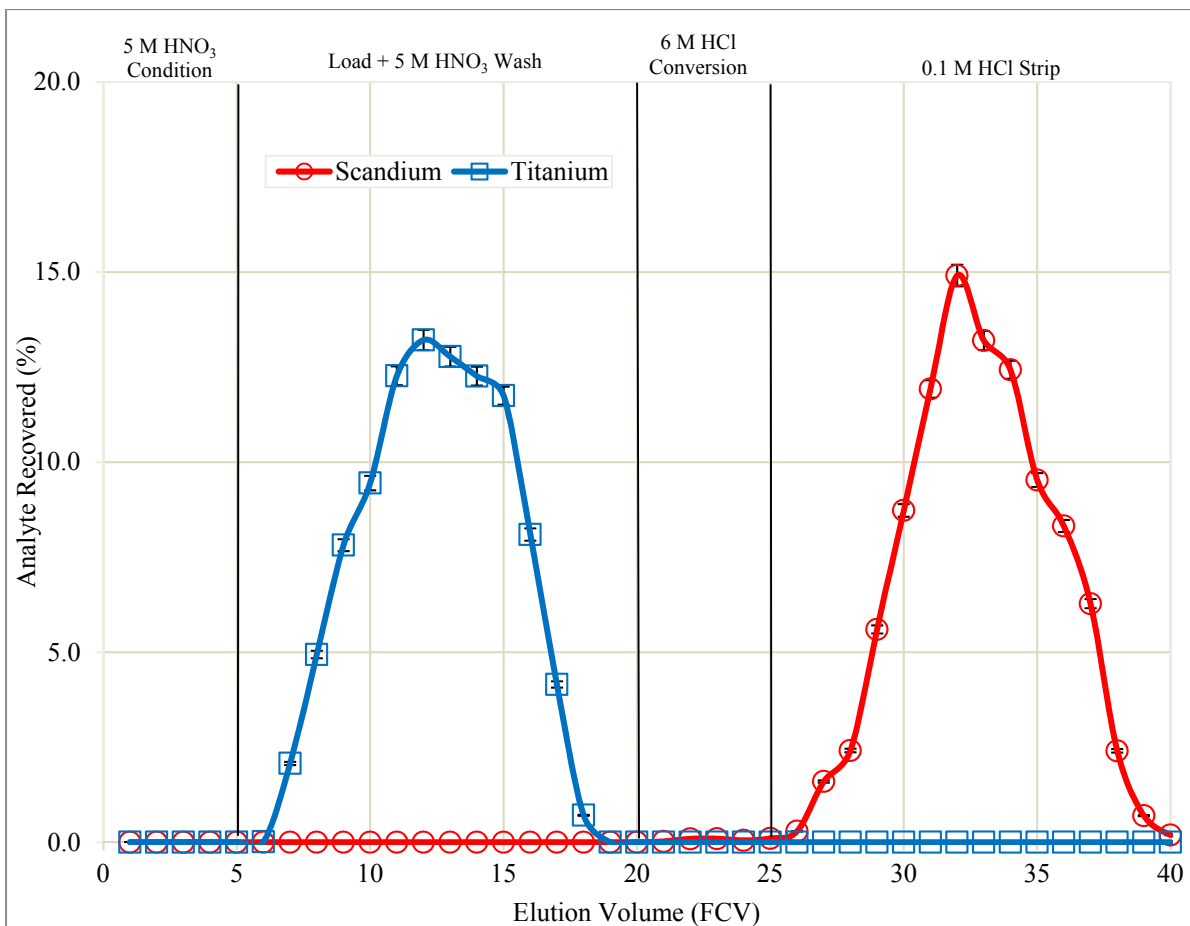

Figure 26: Elution profile for the 1:2 ratio of Sc to Ti gravity column study using wet slurry DGA resin. Analyte recoveries of  $98.62 \pm 1.25\%$  for Sc and  $99.51 \pm 2.22\%$  for Ti.

Table 21: Percent analyte recovery for each elution phase of the 1:2 ratio Sc to Ti elution profile in figure 6.1

Elution Phase	FCV Range	Sc Recovery (%)	1 $\sigma$	Ti Recovery (%)	1 $\sigma$
5 M HNO <sub>3</sub> Condition	1 to 5	<LOD	<LOD	<LOD	<LOD
Load + 5 M HNO <sub>3</sub> Wash	6 to 20	0.04	0.01	99.51	2.22
6 M HCl Conversion	21 to 25	0.26	0.01	0.01	0.01
0.1 M HCl Strip	26 to 40	98.62	1.25	0.02	0.01

Table 22: Decontamination factors for each elution phase of the 1:2 ratio Sc to Ti elution profile in figure 6.1

Elution Phase	DF (Sc/Ti)	1 $\sigma$	DF (Ti/Sc)	1 $\sigma$
5 M HNO <sub>3</sub> Condition	N/A	N/A	N/A	N/A
Load + 5 M HNO <sub>3</sub> Wash	3.52E-04	1.01E-04	2.84E+03	8.15E+02
6 M HCl Conversion	3.94E+01	5.96E+01	2.54E-02	3.85E-02
0.1 M HCl Strip	5.36E+03	2.91E+03	1.87E-04	1.01E-04

The elution profile above shows the column elution spread between four phases or fractions. The first (condition) phase was measured to determine if any residual Sc or Ti was dissolved in the acid solution or part of the resin column. Recovery of both analytes were below the detection limit of 0.01 ppb or 0.01% relative to the feed stock. The second (load plus wash phase) shows  $99.51 \pm 2.22\%$  of the Ti eluting off the column while nearly all of the Sc remained sorbed to the column. In this phase, the decontamination factor (DF) of Ti was 2.84E3 as only 0.04% of the Sc eluted off. The third (conversion) phase shows less than 1% elution of Ti or Sc as shown in table 13. This phase was important to determine if there would be any bleed over of Ti from the 2<sup>nd</sup> phase. In the fourth (stripping) phase,  $98.62 \pm 1.25\%$  of the Sc was eluted off the column with less than 1% of the Ti stock. The DF for Sc was 5.36E3 for this phase as only 0.02% of Ti was eluted. Overall,  $98.62 \pm 1.25\%$  of the Sc was recovered during the strip step and  $99.51 \pm 2.22\%$  of the Ti was recovered during the load plus wash step. Less than 0.3% of the Sc was shown to elute during the condition step which is likely due to the dilution of added 6 M hydrochloric acid to the resin bed volume of 5 M nitric acid in the column from step 2.

The results for the for the 1:100 Sc to Ti gravity column study using wet slurry DGA resin is shown below in figure 27. Note that neither the wash phase or conversion phase is shown as the Sc and Ti recoveries were below 1%. The percent recovery of each analyte by elution phase is shown in table 23 while the decontamination factor for each phase is shown in table 24.

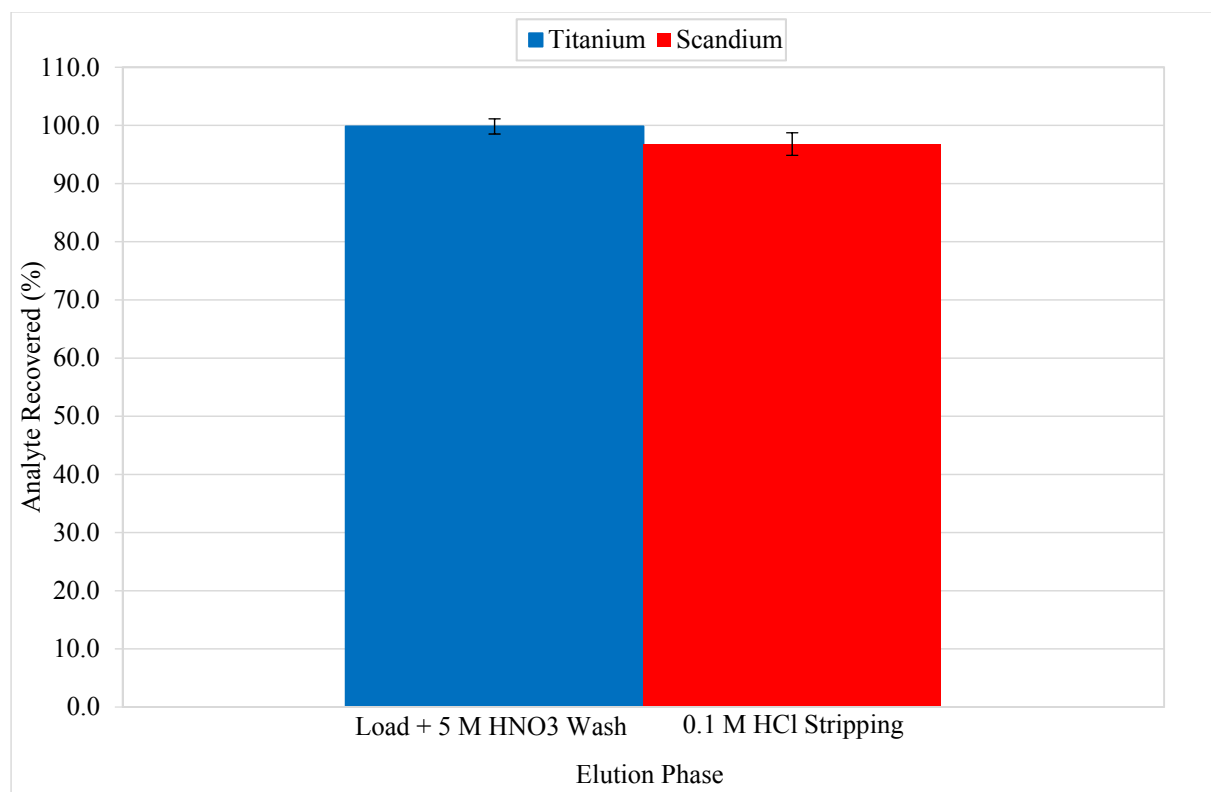

Figure 27: Gravity column elution fraction study for the 1:100 ratio of Sc to Ti using wet slurry DGA resin

Table 23: Percent analyte recovery for each elution phase using a 1:100 ratio of Sc to Ti

Elution Phase	Sc Recovery %	1 $\sigma$	Ti Recovery %	1 $\sigma$
Load + 5 M HNO <sub>3</sub> Wash	2.23E-03	4.45E-05	99.82	1.30
6 M HCl Conversion	5.56E-04	1.11E-05	0.063	0.001
0.1 M HCl Strip	96.79	1.94	3.61E-03	7.21E-05

Table 24: Decontamination factors for each elution phase using a 1:100 ratio of Sc to Ti

Elution Phase	DF (Sc/Ti)	1 $\sigma$	DF (Ti/Sc)	1 $\sigma$
Load + 5 M HNO <sub>3</sub> Wash	2.23E-05	5.32E-07	4.49E+04	1.07E+03
6 M HCl Conversion	8.90E-03	2.52E-04	1.12E+02	3.18E+00
0.1 M HCl Strip	2.68E+04	7.59E+02	3.73E-05	1.05E-06

Adaption of first gravity column study using a higher mass loading of titanium at a 1:100 ratio of Sc to Ti showed high recoveries for both analytes. In this method, the Ti mass was increased by a factor of 10 while Sc was lowered from 5 to 1 mg. In the load plus wash fraction,  $99.82 \pm 1.30\%$  Ti was recovered with a DF for Ti of 4.49E4. In the conversion phase, less than 1% of either analyte was measured. In the strip phase,  $96.79 \pm 1.94\%$  of Sc was recovered with a DF for Sc of 2.68E4.

#### 6.4.2 Vacuum Column Studies

The results for the vacuum column studies using a 1:100 Sc to Ti ratio solution in DGA resin cartridges at varying flow rates are shown below in figure 28. Similar, to figure 27, the conversion phase is not shown as the measured concentration of either analyte was less than 1% in each study. The decontamination factors for each elution phase in each study are shown below in tables 25, 26, and 27.

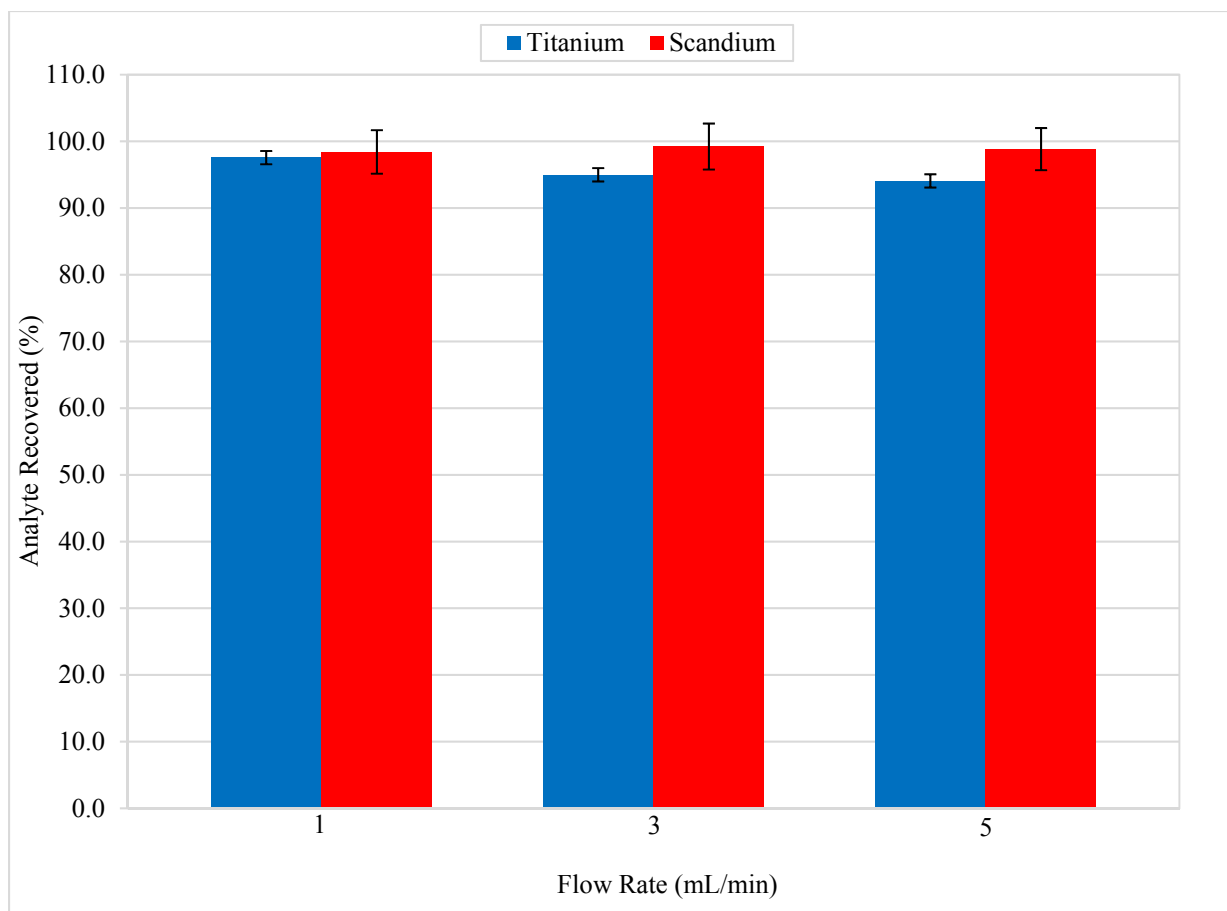

Figure 28: Vacuum column studies separating Sc from Ti at a 1:100 ratio using prepacked DGA resin cartridges at various flow rates

Table 25: Decontamination factors for each elution phase using a 1:100 ratio of Sc to Ti at a flow rate 1 mL/min

Elution Phase	DF (Sc/Ti)	1 $\sigma$	DF (Ti/Sc)	1 $\sigma$
Load + 5 M HNO <sub>3</sub> Wash	1.88E-05	1.31E-05	5.32E+04	3.71E+04
6 M HCl Conversion	4.90E-02	2.63E-02	2.04E+01	1.09E+01
0.1 M HCl Strip	6.03E+04	4.57E+04	1.66E-05	1.26E-05

Table 26: Decontamination factors for each elution phase using a 1:100 ratio of Sc to Ti at a flow rate 3 mL/min

Elution Phase	DF (Sc/Ti)	1 $\sigma$	DF (Ti/Sc)	1 $\sigma$
Load + 5 M HNO <sub>3</sub> Wash	6.45E-06	1.72E-06	1.55E+05	4.14E+04
6 M HCl Conversion	1.17E+00	1.02E+00	8.57E-01	7.50E-01
0.1 M HCl Strip	6.51E+04	4.08E+04	1.54E-05	9.61E-06

Table 27: Decontamination factors for each elution phase using a 1:100 ratio of Sc to Ti at a flow rate 5 mL/min

Elution Phase	DF (Sc/Ti)	1 $\sigma$	DF (Ti/Sc)	1 $\sigma$
Load + 5 M HNO <sub>3</sub> Wash	2.10E-05	1.20E-05	4.77E+04	2.72E+04
6 M HCl Conversion	1.07E-01	5.62E-02	9.37E+00	4.93E+00
0.1 M HCl Strip	6.36E+03	4.76E+03	1.57E-04	1.18E-04

Adaption of the 1:100 Sc to Ti gravity column study to vacuum column studies at flow rates of 1, 3, and 5 mL/min showed high recoveries. An average  $\sim 99 \pm \sim 3\%$  Sc was recovered in the stripping phase between the flow rates. An average  $\sim 95 \pm \sim 3\%$  Ti was recovered in the load phase between the flow rates. The DF for Ti in each load plus wash phase showed at least  $10^4$  at all three flow rates while the DF for Sc in each strip phase showed at least  $10^3$  at all three flow rates. Recovery of Sc remained consistent between each run while Ti decreased a few percent as the flow rate increased from 1 to 5 mL/min. At a flow rate of 1 mL/min,  $97.56 \pm 3.53\%$  of the Ti was recovered in the load/wash phase which decreased to  $94.07 \pm 3.21\%$  at rate of 5 mL/min. This decrease seen may be due to the loss to the walls of the column or trapped in the resin bed. This issue was likely seen only in Ti due to the significantly higher mass loading.

## 6.5 Conclusion

Conversion of the batch contact studies to wet slurry studies show a successful separation at low concentrations of Sc (5 mg) and Ti (10 mg). The elution profile shown in figure 26, showed a clean separation between phases with  $99.51 \pm 2.22\%$  of the Ti eluting in the load plus wash phase and  $98.62 \pm 1.25\%$  of the Sc eluting in the strip phase. An increase in mass loading of Ti (100 mg) at a ratio of 1:100 Sc to Ti showed a similar recovery. This ratio was determined in chapter 4 based on the Flattop irradiation of Ti foil. Similar results were shown for the elution fraction study showing  $99.82 \pm 1.30\%$  Ti recovery with a DF for Ti of  $4.49E4$  in the load plus wash phase while showing  $96.79 \pm 1.94\%$  of Sc recovery in with a DF for Sc of  $2.68E4$  in the strip phase.

Adaption of the gravity column studies to vacuum column studies using prepacked resin cartridges showed similar recovery and decontamination factors at flow rates of 1, 3, and 5 mL/min opposed to a flow rate of 0.25 mL/min. The average recovery between the flow rates for Sc was  $\sim 99 \pm \sim 3\%$  and  $\sim 95 \pm \sim 3\%$  for Ti. At the highest flow rate of 5 mL/min, Sc had a recovery of  $98.4 \pm 3.1\%$  with a DF of  $6.36E3$  in the strip phase while Ti had a recovery of  $94.07 \pm 2.7\%$  with a DF of  $4.77E4$  in the load plus wash phase.

Overall, the scale up from gravity column studies at flow rates of 0.25 mL/min and resin precondition times of a few hours required at least 4 hours to separate the 1:2 Sc to Ti solution while at least 5 hours to separate the 1:100 Sc to Ti solution. Successful scale up in mass and use of gravity columns up to flow rates of 5 mL/min would allow for significantly faster separation times by conditions resin cartridges in less than 5 minutes followed by separating the stock solution in less than 30 minutes. The next step in this research would be the application of the vacuum

column method to a sample of activated titanium foil to attempt purification of  $^{46-48}\text{Sc}$  for future use in artificial glass production. Application of this method shown should be successful as the chemistry properties of this separation should not change based on the use radioactive isotopes of Sc and Ti.

## CHAPTER 7: DEVELOPMENT OF A SOLVENT EXTRACTION SYSTEM USING TRIOCYTLAMINE FOR SEPARATION OF MANGANESE FROM CHROMIUM

### 7.1 Introduction

As described previously in chapter 1,  $^{52}\text{Mn}$  has the potential application for use in positron emission tomography (PET) as a positron emitter due to its comparable energy and longer half-life of ~5.6 days. Commonly used positron emitters such as  $^{19}\text{F}$  or  $^{13}\text{C}$  have similar decay energies but half-lives shorter than a few hours requiring medical cyclotrons and separation laboratory in or near each hospital using these isotopes for medical diagnostics.

The method for producing  $^{52}\text{Mn}$  requires separation from  $^{52}\text{Cr}$  or  $^{\text{nat}}\text{Cr}$  (~83%  $^{52}\text{Cr}$ ) that has been activated using the p-n reaction. In this chapter, the solvent extraction studies performed in this chapter will use stable Mn and Cr as the chemical separation technique utilized will not differ based on which isotope was used. Based on previous work, a solvent extraction was performed on Mn and Cr using trioctylamine (TOA) in cyclohexane at varying strong acid concentrations.<sup>61</sup> Additionally studies were performed testing the kinetics of extraction followed by determination and reduction of the third phase formation in each system.

In these studies, a separate analysis method was developed for to measure Cr in solution. Stock solutions used in this research were prepared from ICP-MS grade standards containing  $^{\text{Nat}}\text{Cr}$  (83.8%  $^{52}\text{Cr}$ ). In these studies organics and hydrochloric acid were used causing isobaric interferences through the formation of  $^{40}\text{Ar}^{12}\text{C}^+$  and  $^{35}\text{Cl}^{16}\text{OH}^+$  when measured on a ICP-MS. Complexes formed in the instrument filter through and create a false signal requiring a separate measurement method using a discrete reaction cell. To reduce false signal, the system is purged with a reactive gas forming stable known compounds which can be filtered from detection.<sup>83</sup> Based

on initial measurements using a standard quadrupole without reaction cell, at ppb quantities of Cr, interferences of 5 to 50 times the standard concentration were measured.

## **7.2 Materials**

All materials used in this chapter are shown in section 3.1.

## **7.3 Experimental Procedure**

### **7.3.1 Solvent Extraction Study**

The general solvent extraction method used is described in section 3.3.1. Two variants of the general method were employed to test the extractability of Mn and Cr from acid solutions.

In the first variant, the organic ligand concentration was kept static based on previous work performed by Lahiri<sup>61</sup>. A stock solution of 0.8 M TOA ligand dissolved in cyclohexane and 2% (v/v) 1-octanol was produced. Multiple stock solutions containing 250 ppb of Cr and Mn in 0.01-10 M hydrochloric acid were produced using certified standards. In a 2 mL vial at each acid concentration, 0.75 mL of 250 ± 1% ppb Cr and Mn stock solution was added followed by 0.75 mL of the 8 M TOA stock solution so the total volume was 1.5 mL. Each vial was placed on a Labquake shaker table for 1 hour. After mixing, the vials were placed upright to allow immiscible phases to reform. An aliquot was taken from the aqueous layer, diluted, and measured on the NexION ICP-MS described below in 7.3.1.2. This method was duplicated using stock solutions in 0.01-10 M nitric acid. However, TOA stock solutions contained 3% (v/v) octanol in the nitric acid method.

In the second variant, In the second variant, the acid concentration was kept static while the ligand concentration was variable. The same procedure was performed as above using 9 M hydrochloric or nitric acid and a range of 0.01 to 0.8 M TOA ligand. An aliquot was taken from

the aqueous layer, diluted, and measured on the NexION ICP-MS described below in 7.3.1.2. Determination of the octanol volume used was determined in section 7.3.3 below. Both experiments were replicated in triplicate at each varied acid or TOA concentration.

#### **7.3.1.1 NexION 350 ICP-MS Method**

The general measurement procedure for the NexION 350 ICP-MS was used and is described in section 3.3.1.2. Additionally, studies performed in hydrochloric acid were diluted by a factor of 100 to reduce chloride interference before introduction into the reaction cell. Ammonia gas was used to react and filter out isobaric interferences caused by  $^{40}\text{Ar}^{12}\text{C}^+$  and  $^{35}\text{Cl}^{16}\text{OH}^+$  prior to analysis. This method was repeated in nitric acid to reduce the  $^{40}\text{Ar}^{12}\text{C}^+$  isobaric interference and for consistency between measurement methods.

#### **7.3.1.2 Data Analysis**

The data was analyzed using the method shown in section 3.3.1.2.

### **7.3.2 Kinetic Study**

The kinetic study method duplicated the solvent extraction procedure described in section 7.3.1.1 using only 0.8 M TOA, 9 M nitric, and 9 M hydrochloric acid. Samples were mixed for 10, 30, or 60 minutes followed by 5 minutes to allow phase reformation. An aliquot of 0.5 mL was taken from the aqueous phase of each sample, diluted to 15 mL using 2% nitric acid and measured on the NexION 350 ICP-MS using the method described in 7.3.1.2 above. The study was performed in triplicate.

#### **7.3.2.2 Data Analysis**

The data was analyzed by the same method shown in section 7.3.1.3.

### **7.3.3 Third Phase Formation Study**

The third phase formation procedure was adapted from the solvent extraction procedure in section 7.3.1.1 without the use of Cr or Mn in the aqueous phase and only TOA ligand and cyclohexane in the organic phase. This method was used to determine the quantity of 1-octanol needed for the solvent extraction phase above in 7.3.1.1. A solution of 0.01, 0.1 and 0.8 M TOA in cyclohexane was produced. A stock of 0.1, and 10 M hydrochloric and nitric acid was produced. In a 15 mL centrifuge vial, 7 mL of 0.01 M TOA stock and 7 mL of 0.1 M hydrochloric acid was added. This was repeated for using 0.01 M TOA with 10 M hydrochloric acid followed by 0.1 and 0.8 M TOA with both acid concentrations. Each solution was mixed for 30 minutes on a shaker table to determine if a third phase would form. In solutions where one formed, a single drop of 1-octanol was added a pasteur pipette followed by vigorous mixing by hand for 30 seconds. The vial was set upright to see if the two or three phases would reform. This process was repeated until the third phase was disappeared. This entire method duplicated using 0.1 and 10 M nitric acid. For each acid/ligand concentration, the process was repeated in triplicate. The number of drops were recorded for each ligand/acid concentration in each run. Using the same Pasteur pipette, the average mass of one drop of 1-octanol was weighed on a laboratory scale by averaging the mass of 10 drops.

#### **7.3.3.2 Data Analysis**

The data was analyzed using the method described in section 3.3.2.

## 7.4 Results and Discussion

### 7.4.1 Solvent Extraction Studies

#### 7.4.1.1 Varied Acid Concentration Studies

The distribution ratio results of solvent extraction studies using 0.8 M TOA at varied nitric and hydrochloric acid concentration are shown below in figures 29, and 31. The results of these studies in percent extraction are shown below in figures 30 and 32.

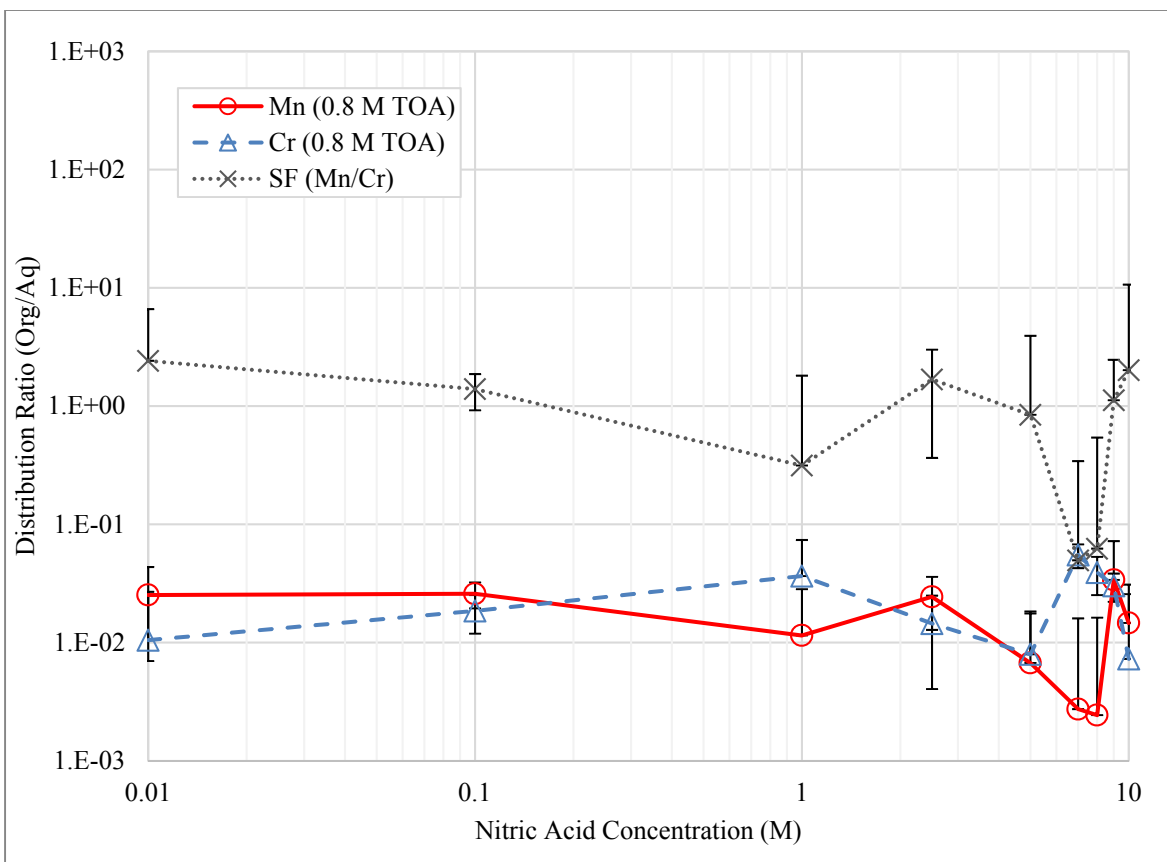

Figure 29: Solvent extraction study of Mn and Cr using 0.8 M TOA at varied nitric acid concentrations

In figure 29, both analytes showed little to no distribution with ratios under 0.1 at any concentration of nitric acid. In low acidic solution,  $Mn^{2+}$  will form  $Mn(OH)_2$  or  $MnO$  with an increasing shift to  $Mn(NO_3)_2$  as the nitrate concentration increases.<sup>38,56</sup> The formation of the  $Mn(NO_3)_2$  is weakly bound and should likely be extracted by the amine electron donor. This is not the case as the distribution ratio in nitric acid is low across the entire range possibly due to additional competing interactions. Trivalent  $Cr^{3+}$  at low nitric acid concentration forms  $Cr_2O_3$  due to a strong binding to water molecules which prevents extraction into the organic phase due to the hydrophobic nature of water.<sup>41</sup> This strong binding to water continues to prevent extraction as the nitrate concentration increases. At nitric concentrations above 10 M, a significant quantity of  $Cr(NO_3)_3$ <sup>38</sup> may form and potentially extract although this was not studied here. Significant overlap occurred between both analytes across the entire range. In nitric acid, neither analyte was extracted as the separation factors varied from 0.1 to 2 with larger uncertainties than the value in most cases. Ideally, the separation factor should be at least in the hundreds based on the purity required.

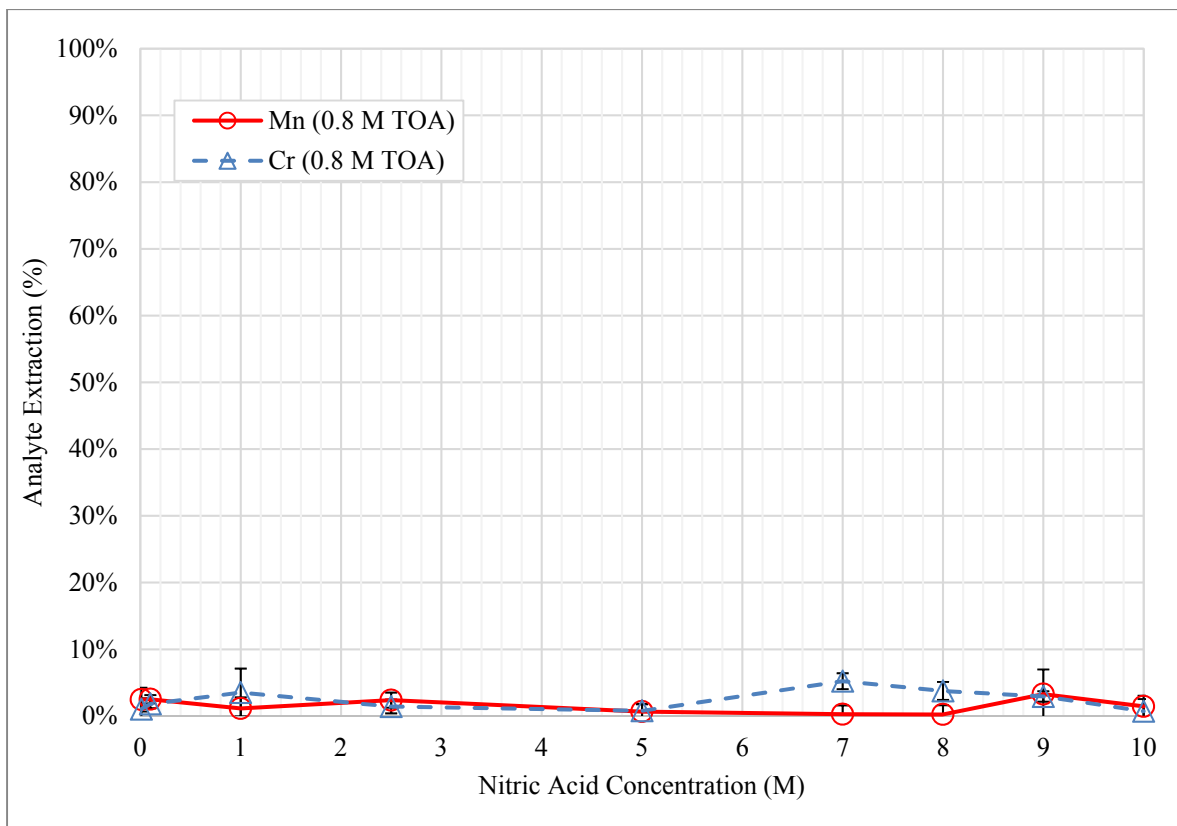

Figure 30: Percent analyte extraction of Mn and Cr using 0.8 M TOA at varied nitric acid concentrations

In figure 30, percent extraction values for Mn and Cr are shown based on the distribution values determined for figure 7.1. Less than 5% of either analyte was extracted at any nitric acid concentration. Any extraction shown does not follow a trend is likely due to human error or data processing as the uncertainty shown for each acid concentration are less than 3% which is determined by comparing replicates in the same experiment. The fluctuations seen seem to be due to statistical drift of all replicates at each acid concentration.

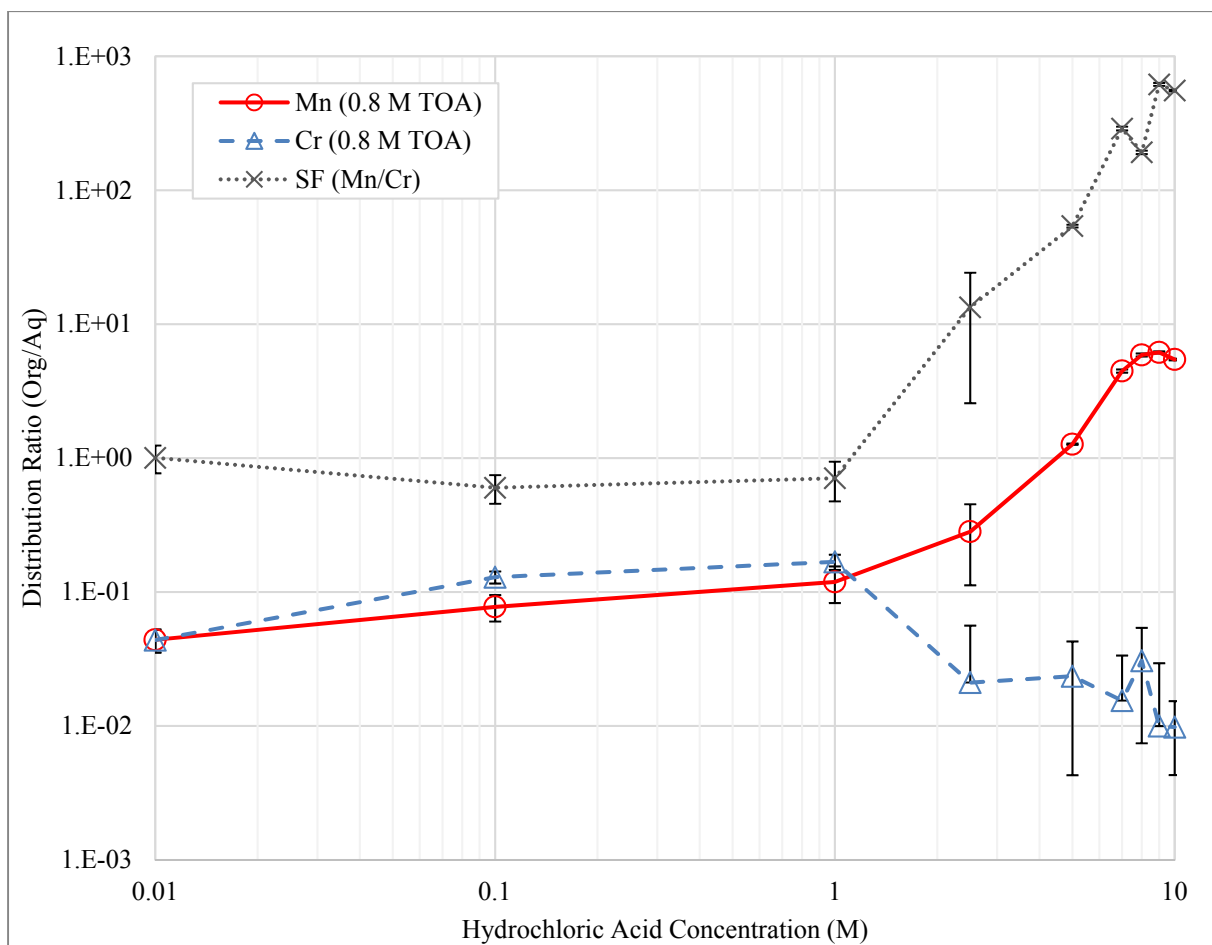

Figure 31: Solvent extraction study of Mn and Cr using 0.8 M TOA at varied hydrochloric acid concentrations

In figure 31, the distribution ratios of Mn and Cr were similar with a slightly increasing trend from 0.01 to 1 M hydrochloric acid. At 1 M, the slopes diverged with the distribution of Mn increasing rapidly up to a value of ~6 from 8 to 10 while Cr showed a decrease in distribution ratio to ~0.02 from 8 to 10 M. In hydrochloric acid, divalent Mn forms anionic species as the chloride concentration increased from  $\text{MnCl}_2$  up to 5 M followed by the anion  $\text{MnCl}_3^-$  at above 6 M.<sup>56</sup> The anionic species formed are fairly weak and can be easily knocked off<sup>58</sup> once the hydrochloric acid concentration reach 1 M. Similar to the nitric acid system, Cr is strongly bound to water and likely could not be extracted. The trend seen showing the Cr distribution slightly increasing may be due

to other mechanisms at low acid such as adherence to the container while from 1 M up the dominant species was  $\text{Cr}_2\text{O}_3$ . However, across the entire range, a distribution of 0.1 is not very significant and may be due to human error. The separation factor of Mn to Cr show little change from 0.01 to 1 M followed by a rapid increase up to  $616.7 \pm 15.4$  at 9 M.

Figure 32: Percent analyte extraction of Mn and Cr using 0.8 M TOA at varied hydrochloric acid concentrations

In figure 32, percent analyte extraction for Mn and Cr are shown based on the distribution values from figure 31. The single extraction of Mn showed a slight increase in from 0.01 to 2.5 M hydrochloric acid followed by a rapid increase up to ~85% at 8 to 10 M. Alternatively, Cr increased from ~5 to 15% extraction up to 1 M followed by a rapid decrease to 2.5 M where percent

extraction remained below 3% up to 10 M. The slight increase in Cr extraction shown from 0.1 to 1 M hydrochloric acid is likely due to an alternative mechanism such as sorption to the container walls through hydrogen bonding. This mechanism is corrected once the chloride concentration increases from 1 M up to 10 M hydrochloric acid.

#### **7.4.1.2 Varied TOA Concentration Studies**

The distribution ratio results of the solvent extraction study using 9 M hydrochloric or nitric acid at varied TOA ligand concentration are shown below in figures 33, and 35. Percent extraction results for Mn and Cr based on these distribution ratio values are shown in figures 34, and 36.

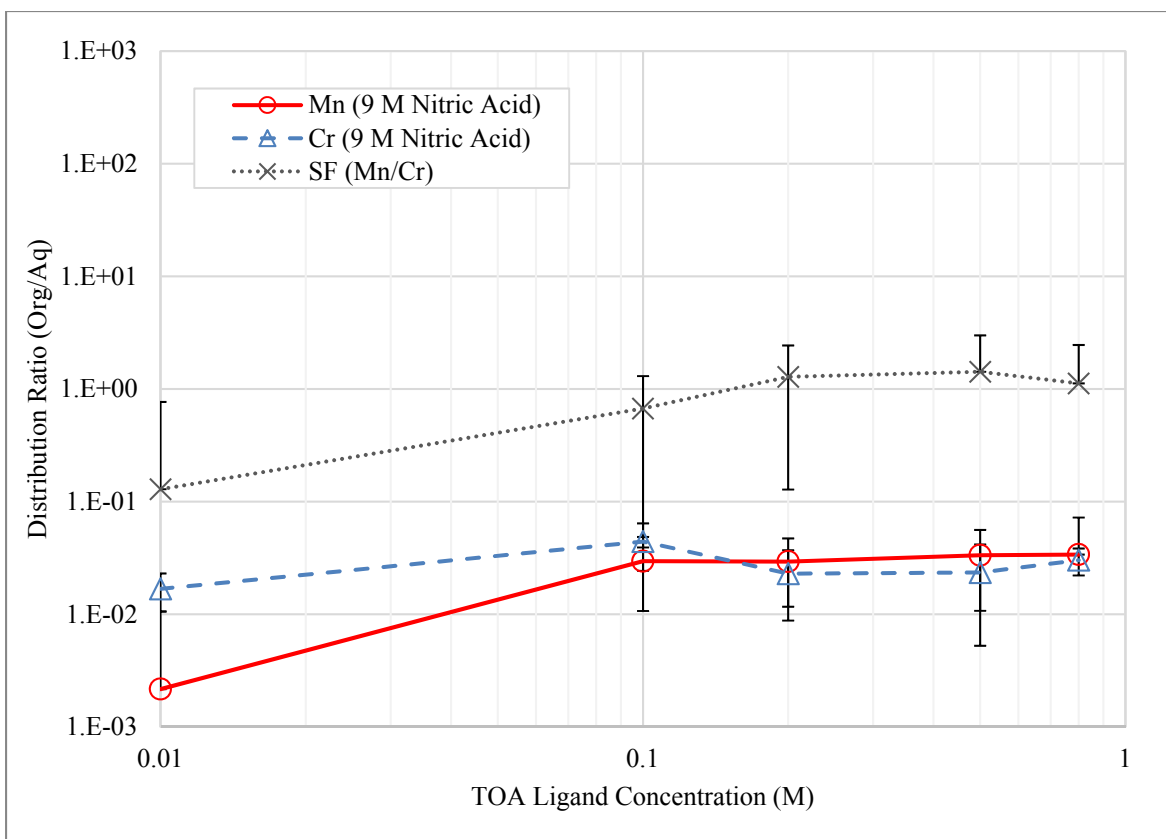

Figure 33: Solvent extraction study of Mn and Cr using 9 M nitric acid at varied TOA ligand concentrations

In figure 33, a very low distribution ratio was shown for Mn and Cr across the entire TOA concentration range in nitric acid. This is similar to what was shown in figure 29,  $Mn(NO_3)_2$  did not extract at any concentration of ligand. Similarly, Cr did not extract due to a strong bonding to water molecules across the acid range. The distribution trend shows a slight increase occurred for both analytes from 0.01 to 0.1 M meaning that there might be a slight extraction occurring based on the order of magnitude increase in ligand concentration. This increase becomes flat from 0.1 to 0.8 M TOA meaning that a further increase in TOA ligand may not change the extraction. The lack of extraction for both species is likely due to the species formed in nitric acid.

Figure 34: Percent analyte extraction of Mn and Cr using 9 M nitric acid at varied TOA ligand concentrations

In figure 34, the distribution ratios from figure 33 were converted to percent extraction showing less than 5% extraction of either analyte at any concentration of ligand. This is similar to what was shown in figure 30, showing a slight extraction once the TOA concentration reaches 0.1 M. However, this extraction plateaus at 0.1 M so it is unlikely that a further increase in ligand concentration would affect extraction.

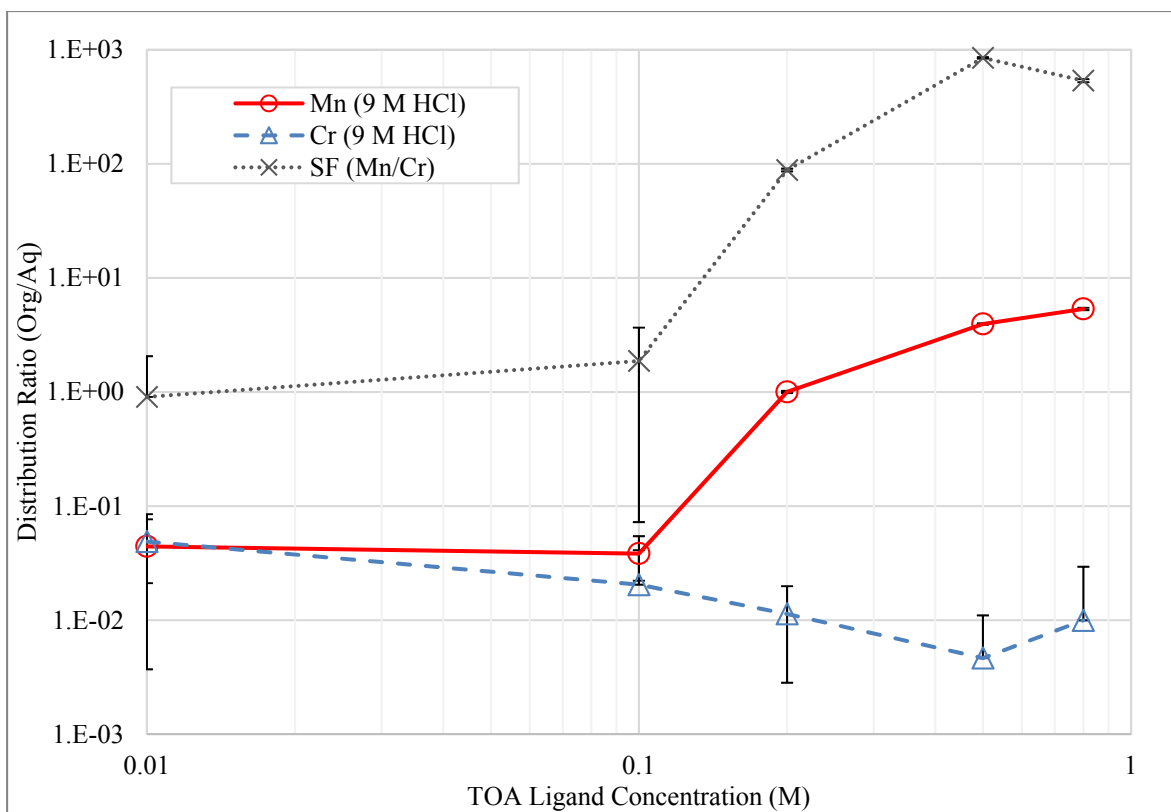

Figure 35: Solvent extraction study of Mn and Cr using 9 M hydrochloric acid at varied TOA ligand concentrations

In figure 35, the distribution ratio of Cr and Mn showed a similar extraction from 0.01 to 0.1 M TOA in 9 M hydrochloric acid. From 0.1 up to 0.8 M TOA, the distribution ratio for Mn increased up to a distribution ratio of 5.35 at 0.8 M TOA similar to ~6 in figure 31. Alternatively, Cr showed a steady decreased down to 0.01 at 0.8 M TOA. Similar to plot 34, it seems that greater than 0.1 M TOA ligand is need to begin extraction of  $MnCl_2$ . The mechanism is ligand that of two unidentate amine ligands donates electron density to the Mn center while pushing off the weak chloride anions. Cr does not show extraction due to strong binding with water molecules preventing migrating to the hydrophobic organic layer. The separation factor showed little change from 0.01 to 0.1 M followed by a rapid increase up to ~800 at 0.5 M TOA due to a lower Cr

distribution relative to the study shown in figure 31. At 0.8 M, the separation factor was  $536.2 \pm 16.2$  which was only slightly smaller than  $616.7 \pm 15.4$  shown previously. The deviation between these values is only  $13.9 \pm 3.6\%$  and would likely be reduced through repetition of each study.

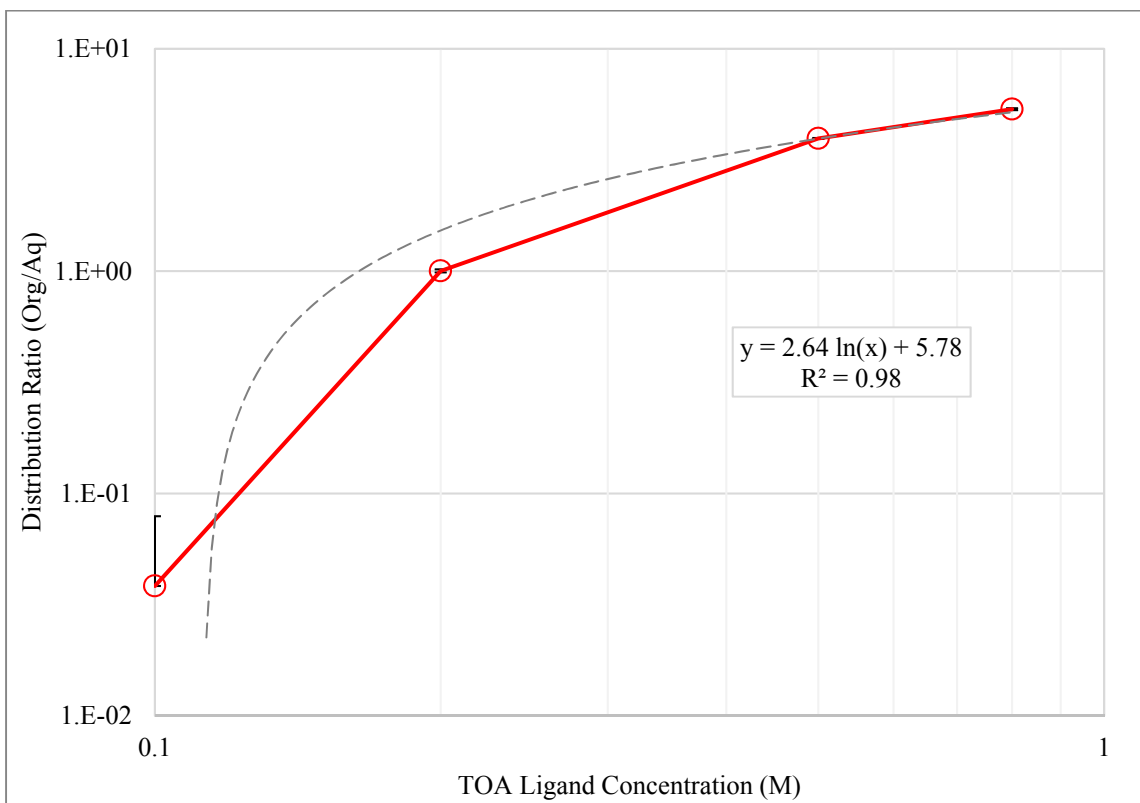

Figure 36: TOA ligand to Mn coordination determination using a 9 M hydrochloric acid solvent extraction system

In figure 36, the Mn distribution relative to the TOA concentration was compared using the data from figure 35 to determine the number of TOA ligands coordinating to each Mn analyte in 9 M hydrochloric acid. As the distribution between the two phases increases, the slope in the log fit equation determined that the complexation occurs at a ratio of 2.64 TOA ligands to 1 Mn atom as the ligand concentration increases. This value is the empirical value based on the

complexation of multiple species. As the ratio is larger than 2, Mn would likely be extracted as a neutral species through additional mechanism in addition to coordination of two unidentate tertiary amines (TOA) for each metal center. It is possible that dimer is being formed between two metal centers and more than two unidentate ligands pushing off the chloride species. This proposed dimer species may explain why little extraction occurred in the nitric acid system as a nitrate dimer system may be more strongly bound sharing five  $\text{NO}_3^-$  groups in addition to having have greater steric hindrance preventing coordination.

Figure 37: Percent analyte extraction of Mn and Cr using 9 M hydrochloric at varied TOA ligand concentrations

In figure 37, percent analyte extraction for Mn and Cr are shown based on the distribution values from figure 32. Mn showed little extraction from 0.01 to 0.1 M TOA followed by a rapid increase up to ~85 like in figure 31. Similarly, less than 5% of Cr was extracted across the entire range. This differs from figure 32, where Mn and Cr showed ~15% extraction from 0.01 to 0.1 M hydrochloric acid. The difference is likely that at low acid concentration a mixed species is formed causing an alternative mechanism for loss. This may be due to sorption to the container walls or slight precipitation of either analytes oxide form followed by dissolution as the chloride concentration increases.

#### 7.4.2 Kinetic Solvent Extraction Studies

The results of the kinetic extraction studies for 1 and 10 M nitric and hydrochloric acid are shown below in tables 28 and 29.

Table 28: Kinetic solvent study of Mn and Cr in HNO<sub>3</sub>

HNO <sub>3</sub>	Time (Minutes)	$D_{Mn}$	1 $\sigma$	$D_{Cr}$	1 $\sigma$	SF (Mn/Cr)	1 $\sigma$
1 M	10	0.02	0.02	0.01	0.02	1.23	2.01
1 M	30	0.01	0.01	0.02	0.01	0.75	0.93
1 M	60	0.01	0.01	0.01	0.02	1.18	1.68
10 M	10	0.01	0.01	0.01	0.01	0.58	0.84
10 M	30	0.004	0.005	0.01	0.01	0.51	0.77
10 M	60	0.01	0.01	0.003	0.005	2.45	4.22

In table 28, there was little to no change in distribution ratio and separation factor across based on the amount of time mixed on the shaker table. The distribution ratios measured had extremely high uncertainty based on the initial measurements. The uncertainty on each value

increased significantly higher due to error propagation during the data analysis. The kinetic data shown follows what was shown in the previous nitric acid studies shown in the previous section.

Table 29: Kinetic solvent study of Mn and Cr in HCl

HCl	Time (Minutes)	$D_{Mn}$	1 $\sigma$	$D_{Cr}$	1 $\sigma$	SF (Mn/Cr)	1 $\sigma$
1 M	10	0.25	0.06	0.24	0.04	1.02	0.29
1 M	30	0.23	0.08	0.22	0.08	1.03	0.32
1 M	60	0.18	0.17	0.20	0.12	0.95	0.39
10 M	10	5.39	0.06	0.010	0.001	544.67	53.39
10 M	30	5.70	0.12	0.010	0.001	570.58	70.92
10 M	60	5.97	0.03	0.010	0.002	590.79	95.82

In table 29, the distribution ratio of both analytes did not change significantly as mixing time increased from 10 to 60 minutes. In 1 M hydrochloric acid, the separation factor fluctuated around  $\sim 1$ . This is due to lack of chloride concentration causing formation of the weakly anionic  $MnCl_2$ . In the low acid system, the  $MnO$  or  $Mn(OH)_2$  seems to be more strongly bound preventing extraction. At 10 M hydrochloric acid, Cr shows a strong distribution of 5.39 to 5.97 while Mn shows a decrease in distribution relative to the 1 M study. It is likely that this decrease occurs due to lack of mixed species where at low acid concentration, partial loss or extraction of Cr is possible. The SF at 10 M hydrochloric acid shows a slight increase from 544.67 at 10 minutes to 590.79 at 60 minutes. The deviation between these values is  $8.12 \pm 1.54\%$  which may decrease by repetition of the kinetic studies. In further studies, the kinetics of mixing for lengths of time greater than one hour to determine if a larger SF is possible. An increase in SF would potentially increase the percent extracted from each solvent extraction requiring fewer additional extractions to acquire greater than 90% recovery. Based on this data, 10 minute mixing time is likely sufficient for

qualitative or semi quantitative extraction while one or more hours should be used to for a quantitative separation.

### 7.4.3 Third Phase Studies

The results of the third phase studies are shown below in tables 30 and 31. In both acid matrices, no third phase formation occurred at 0.01 M TOA at any acid concentration.

Table 30: Percent octanol needed to reduce third phase formation in HCl

HCl	0.01 M TOA	1 $\sigma$	0.1 M TOA	1 $\sigma$	0.8 M TOA	1 $\sigma$
0.1 M	N/A	N/A	1.43	0.12	2.01	0.19
10 M	N/A	N/A	1.87	0.13	2.09	0.20

In hydrochloric acid, the percent octanol (v/v) needed for third phase removal increased from  $1.43 \pm 0.12\%$  for a 1:1 mixture of 0.1 M TOA to 0.1 M hydrochloric acid to  $2.09 \pm 0.20\%$  for 1:1 mixture of 0.8 M TOA to 10 M acid. For ease in the experimental solvent extraction method, an average of 2% octanol (v/v) was used for all studies using a TOA concentration of 0.1 M and 0.1 M or higher hydrochloric acid. No octanol was used for solvent extraction studies under 0.1 M TOA.

Table 31: Percent octanol needed to reduce third phase in HNO<sub>3</sub>

HNO <sub>3</sub>	0.01 M TOA	1 $\sigma$	0.1 M TOA	1 $\sigma$	0.8 M TOA	1 $\sigma$
0.1 M	N/A	N/A	2.19	0.11	2.81	0.21
10 M	N/A	N/A	2.75	0.16	3.06	0.19

In nitric acid, the percent octanol (v/v) needed for third phase removal was slightly higher than hydrochloric acid at 0.1 and 10 M. For a 1:1 mixture of 0.1 M TOA to 0.1 M nitric acid, 2.19  $\pm$  0.11% was determined up to 3.06  $\pm$  0.19% for a 1:1 mixture of 0.8 M TOA to 10 M acid. For ease in the experimental method, an average of 3% octanol (v/v) was used for all studies at 0.1 M TOA concentration and 0.1 M or higher acid concentration. No octanol was used for solvent extraction studies under 0.1 M TOA.

## 7.5 Conclusion

The solvent extraction method used in this chapter showed increasing distribution ratio in hydrochloric acid using the TOA ligand as either variable was increased. In 0.8 M TOA, the distribution ratio of Mn increased as the chloride concentration increased. This is likely due to the formation of weakly bound MnCl<sub>2</sub> at concentrations above 1 M<sup>56</sup> or MnCl<sub>3</sub><sup>-</sup> at hydrochloric acid concentrations above 6 M. This is due to the electron donating nitrogen on the tertiary amine coordinating to the metal center and pushing off the weak chlorides. At lower acid concentrations, Mn oxide and hydroxide species were dominant preventing extraction. In figure 31, the distribution ratio of Mn was ~0.1 from 0.01 to 1 M, followed by an increase to ~6 from 8 to 10 M. Cr does not form significant complexes hydrochloric acid due to a strong binding to water molecules.<sup>41</sup> The distribution of Cr remained between 0.1 and 0.01 across the acid range. An optimal SF of ~580 was determined in a system using 0.8 M TOA and 9 M hydrochloric acid. In

one separation, the percent extraction recovered for Mn was ~85% from 8 to 10 M. Less than 5% of the Cr was extracted from 1 to 10 M while a slight increase to ~15% extraction was seen below 1 M likely due to other mechanisms extracting Cr such as sorption to the container wall.

A similar trend was seen for both analytes at 9 M hydrochloric acid and a varied TOA ligand concentration. The distribution ratio of Mn increased from 0.04 to 5.35 as the chloride concentration increased from 0.1 to 0.8 M TOA. Below 0.1 M, there was likely insufficient ligand to extract. The distribution rate for Cr ranged from less than 0.1 to 0.01 showing little extraction as the TOA concentration increased. A SF of 536.28 was determined at 0.8 M TOA which is slightly less than the previous study due to a slight decrease in the Mn distribution ratio from ~6 to 5.35. Mn and Cr extracted similarly to before with ~ 85% Mn and less than 5% Cr at 0.8 M TOA. In addition to determining the SF and percent extraction, the distribution ratio of Mn to the TOA ligand concentration from 0.1 to 0.8 M was shown in figure 36. Although, Mn is divalent in solution at these acid conditions, the ligand ratio determined through a log regression showed that a ratio of 2.64:1 TOA ligand to Mn atom was extracted. This may explain why Mn was not extracted in nitric due to other extracted species such a dimer which may be steric hindered preventing extraction. A further explanation is shown above in the discussion.

In a varied nitric acid system using 0.8 M TOA, the distribution ratio of Mn and Cr fluctuated below 0.1 as the nitric acid concentration increased. This was confounding as Mn should have formed nitrate species as the nitric concentration increased extracting at higher acid. It is possible that the competition between the nitrates in solution is stronger than the complex formation between the tertiary amine or that Mn complexes with water preventing extracting into the hydrophobic phase. Also, it is possible that the extraction mechanism differs from a 2 to 1 TOA ligand to Mn metal center but may extract in a dimer form. This is explained further in the

results sections. Similar to in hydrochloric acid, Cr forms strong bonds in water making it difficult to extract in nitric acid at any concentration.

Kinetic studies were performed using 0.8 M TOA in 1 or 10 M nitric or hydrochloric acid. In the nitric acid system, little to no extraction occurred for either analyte in varied acid or mixing conditions. The SF of Mn to Cr was determined to fluctuate between 0.5 and 2.5 with uncertainties higher than each SF factor in many cases. In the hydrochloric acid system, at 1 M acid, the SF varied around ~1 regardless of the mixing time. At 10 M acid, the distribution ratio of Mn increased by a factor of ~20 while the distribution ratio decreased by a factor of ~5. The SF based on time showed an from 544.7 at 10 minutes to 590.8 at 60 minutes which is an improvement of ~8%. Further kinetic studies using longer mixing times should be performed to determine where the equilibrium threshold.

Additionally, the effect of third phase formation was measured using different TOA and acid concentrations. It was found that no octanol was needed below 0.1 M TOA concentration in either acid but an average of ~2% and ~3% octanol (v/v) was required to reduce formation at 0.1 M TOA in hydrochloric and nitric acid. Further work need to be performed to determine a upper limit for use of octanol as previous work has shown large quantities of diluent such as octanol or TBP used for third phase formation can reduce the extraction potential.<sup>29</sup>

The data presented in this chapter showed that Mn can be separated from Cr using 0.8 M TOA in 8 to 10 M hydrochloric acid. The purpose of this work was to develop a solvent extraction method to be used for production of extraction chromatography resins. This will be explored in the next chapter.

## CHAPTER 8: BATCH CONTACT STUDIES OF MANGANESE AND CHROMIUM ON EXTRACTION CHROMATOGRAPHY RESINS FOR SEPARATION METHOD DEVELOPMENT

### 8.1 Introduction

In chapter 8, batch contact studies were performed to characterize Mn and Cr retention on a series of extraction chromatography resins produced by Triskem International based on the TOA ligand solvent extraction studies performed in chapter 7. Adaption of the liquid-liquid solvent extraction system to a extraction chromatography resin system was performed in an attempt to develop a streamlined commercial method reducing organic or mixed organic waste produced. These resins were tested to determine a weight distribution and separation factor using stable Mn and Cr. If successful, this process will be converted to column studies with increased mass loading to separate  $^{52}\text{Mn}$  produced from activated  $^{\text{nat.}}^{52}\text{Cr}$ .

Five different resins were produced using a varied loading of TOA ligand in various solvents, on either Amberchrom or polystyrene divinyl benzene inert support beads. The shorthand name, Triskem name, and resin composition are shown below in table 32. No additional information was provided for any resin due to proprietary reasons.

Table 32: Triskem extraction chromatography resins using trioctylamine (TOA) ligand

Shorthand Name	Triskem Resin Name	Resin Composition
Resin 1	TOA in Cyclohexane	40% 0.8M nTOA in Cyclohexane / 60 % Amberchrom CG71
Resin 2	TOA on PS-DVB	40% nTOA / 60 % PS-DVB (Pure TOA used)
Resin 3	TOA in Toluene	40% 0.8M nTOA in toluene / 60 % Amberchrom CG71
Resin 4	TK201A 170201	70% Amberchrom CG71 / 29% n-TriOctylAmine / 1% 1-Decanole
Resin 5	TK201S 170202	60% Amberchrom CG71 / 37,5% n-TriOctylAmine / 2,5% 1-Decanole

Batch contact studies were performed using each resin in hydrochloric acid in an attempt to replicate the separation factors determined from the solvent extraction studies in chapter 7. An additional batch contact study was performed on resin 1 using nitric acid to ensure that little to no retention occurred for manganese or chromium.

## **8.2 Materials**

All materials used for the work in this chapter are listed in section 3.1. Each extraction chromatography resin used will be referred to by the shorthand name listed in table 32 above.

## **8.3 Experimental Procedure**

### **8.3.1 Batch Contact Studies**

The general procedure for batch studies is described in section 3.4.1. Single and dual analyte (interference) batch studies were performed in 0.01 to 10 M HCl and 0.01 to 10 M HNO<sub>3</sub>. A mass of  $25 \pm 2\%$  mg of resin 1 was weighed into a 2 mL microcentrifuge vial and preconditioned using 1 mL of acid. Vials were mixed for 1 hour and left upright overnight to permit resin swelling. Each vial was spiked with 0.5 mL of a matching acid solution containing  $750 \pm 1\%$  ppb Mn followed by 1 hour of mixing. Each solution was transferred into a syringe with PTFE tip and filtered into a clean 2 mL microcentrifuge vial. An aliquot from each vial was diluted and analyzed on a NexION 350 ICP-MS per section 7.3.1.2. Four replicates were performed for each acid concentration. This method was repeated using  $750 \pm 2\%$  ppb Cr and using a solution containing Mn and Cr at  $750 \pm 2\%$  ppb. The experiment was repeated using nitric acid on resin 1 only. The hydrochloric batch contact study method was repeated using resins 2 through 5.

### 8.3.1 Data Analysis

The weight distribution  $D_w$  was determined in each study using equation 7 per section

3.4.1.2. Each weight distribution  $D_w$  was volume corrected using tables 33 and 34 below.

Table 33: Resin 1 volume corrections in hydrochloric and nitric acid

Resin 1	HCl Volume Lost (%)	1 $\sigma$	HNO <sub>3</sub> Volume Lost (%)	1 $\sigma$
0.1 M	7.67	0.80	8.93	0.53
1 M	7.78	0.41	7.75	0.74
10 M	8.09	0.55	6.13	0.65

Table 34: Volume corrections for resins 2, 3, 4, and 5 in hydrochloric acid

HCl	Resin 2 Volume Lost (%)	1 $\sigma$	Resin 3 Volume Lost (%)	1 $\sigma$	Resin 4 Volume Lost (%)	1 $\sigma$	Resin 5 Volume Lost (%)	1 $\sigma$
0.1 M	7.21	0.67	8.14	0.06	8.81	0.39	6.74	0.65
1 M	7.85	0.53	8.23	0.17	8.53	0.41	7.32	0.37
10 M	8.03	0.87	8.93	0.24	9.11	0.47	8.00	0.37

### 8.4 Results and Discussion

The results of the batch contact study for resin 1 in hydrochloric and nitric acid are shown below in figure 37, and 38. The results of batch contact studies using resins 2, 3, 4, and 5 in hydrochloric acid are further below in figures 39, 40, 41, and 42.

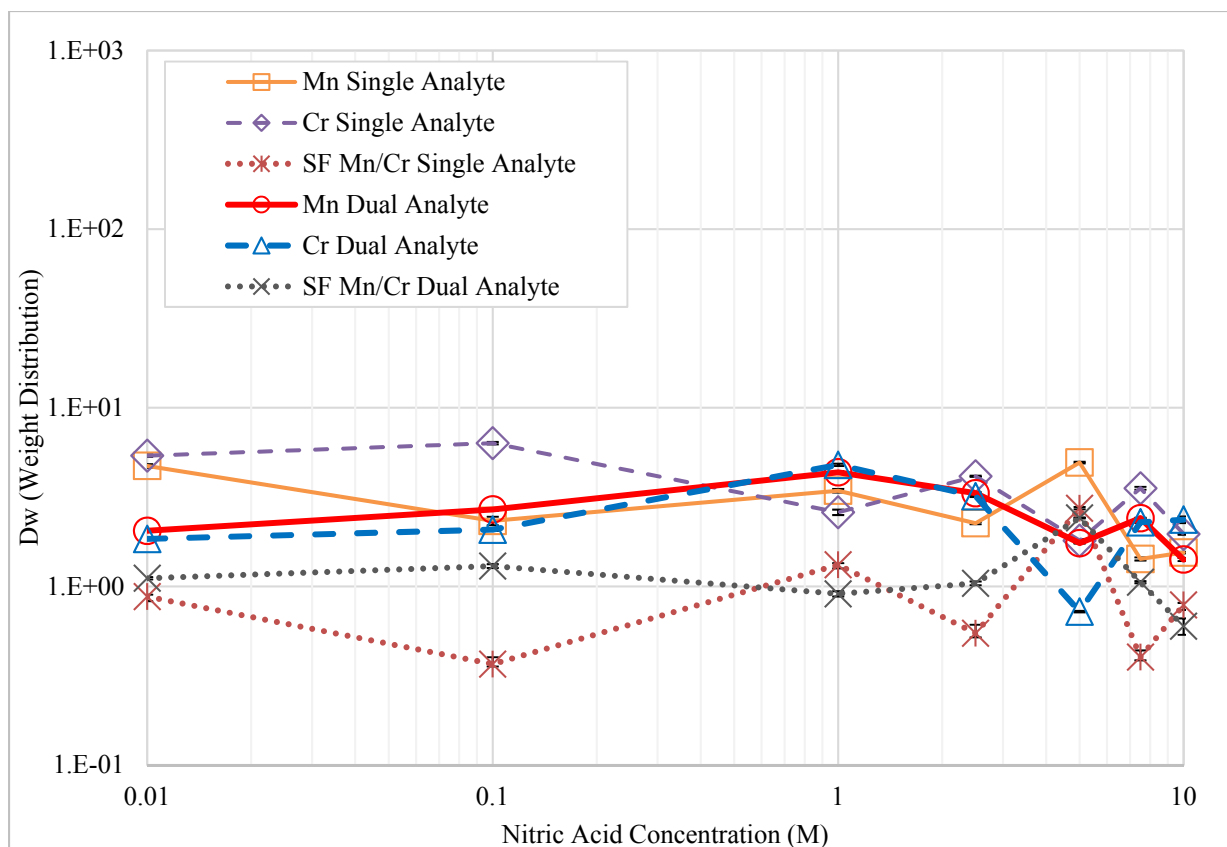

Figure 38: Single and dual analyte batch contact studies using resin 1 in nitric acid

A batch contact study using Mn and Cr was performed using nitric acid to determine if any change in extraction occurred compared to the solvent extraction study performed in chapter 7. The weight distribution  $D_w$  of Mn and Cr overlapped while fluctuating below a value of 10 equivalent to less than ~7.5% retention across the acid range. This was similar to what was seen in the solvent extraction studies for both analytes. No significant variation could be discerned comparing the single and dual analyte weight distributions. The separation factor determined for the single and dual analyte studies ranged from ~0.3 to 3, which is not sufficient to separate Mn from Cr. Ideally, a separation factor of at least 100 if not 1000 is necessary to purify one element from another.

Figure 39: Single and dual analyte batch contact studies using resin 1 in hydrochloric acid

In figure 39, the  $D_w$  of each analyte overlapped significantly showing little retention at any point. The weight distribution and separation fraction for analytes in all studies ranged from ~2 to ~8 which is equivalent to a sorption of ~3 to ~11%. Based on the previous solvent extraction studies, Mn distribution should increase as the chloride concentration increased. Below 1 M, low retention is possible due to a mixture of hydroxide and oxide species. Above 1 M,  $MnCl_2$  and  $MnCl_3^-$  should form followed by extraction by the TOA ligand. Alternatively, it is unlikely that Cr would be extracted into the organic or stationary phase as it preferential binds with water over chloride anions.<sup>41</sup>

Resin 1 produced for this study is composed of 40% 0.8 M TOA ligand in cyclohexane to 60% Amberchrom CG71. Based on previous experience with DGA and Ln resin by Eichrom, 40% loading on Amberchrom CG71 seems like a common choice for resin production. Although, different particle and pore size<sup>35,84</sup> can effect sorption of the resin during production, it is unlikely that significant bleeding occurred when using such a standard method. Additional, studies were performed to weigh out a known quantity of resin 1 into concentrated nitric and hydrochloric acid. These were left out for at least a week to see if any phases would form due to loss of extractant in acid. In addition, no change in retention either increasing or decreasing was seen at higher acids which makes it unlikely that each unidentate ligand was being protonated. The most likely solution is that the quantity of resin used for each resin bead was insufficient for extraction. In resin production, the number of carbons on each ligand in addition to the volume of stationary phase in each pore can decrease extraction if low and potential sterically interact with itself if high. With a similar distribution for Mn and Cr it is unlikely that any extraction was occurring through complexation with the ligand. It is likely that these fluctuations seen are due to another mechanism such as adherence to the container or occlusion within the interstitial space in the form of a neutral species. Additional information is needed about the production to decipher the reason by the lack of extraction.

Figure 40: Single and dual analyte batch contact studies using resin 2 in hydrochloric acid

Similar to figure 40, the  $D_w$  and SF for each analyte in each study showed very low retention with significant overlap while staying below  $\sim 5$  across the acid range. A weight distribution of  $\sim 5$  is equivalent to a sorption of  $\sim 7.5\%$  which is very low. Resin 2 produced for this study using the same loading ratio of 40 to 60% TOA to inert support but used polystyrene divinyl benzene as the support with a unknown pore and particle size. Additionally, no solvent was used in the production method to sorb the ligand to the support. Similar to resin 1, the speciation of the reaction should show Mn extracting as the chloride concentration increases. It is hard to discern if there is a similar issues such as steric hindrance proposed for resin 1, or if there was a production issue caused by bleed off of extractant due to small particle or pore size. It is

feasible that the lack of solvent prevented sorption of the TOA ligand to the inert support. Repetition of these batch contact studies using the exact variation of PS-DVB could potentially determine if the retention seen is due to adherence to the container or the support. Like resin 1, a sample of bulk resin was left in concentrated nitric or hydrochloric acid for a week to see if phases formed due to loss of extractant. However, no phases were seen to form in solution.

Figure 41: Single and dual analyte batch contact studies using resin 3 in hydrochloric acid

Similar to resin 1 and 2, the  $D_w$  and SF for each analyte in single and dual analyte studies showed significant overlap while staying  $\sim 6.5$  across the acid range. A weight distribution of  $\sim 6.5$  is equivalent to a sorption of  $\sim 9.5\%$  although most of the measured weight distribution fluctuated even lower below  $\sim 5$  equivalent to a sorption of  $7.5\%$ . Resin 3 produced is composed of 40% 0.8 M TOA ligand in toluene to 60% Amberchrom CG71. Potentially, this resin should act nearly identical to resin 1 as the only difference in the information given was the choice of solvent. In the process for producing resin, the solvent used should not contribute significantly to production of the resin unless the concentration of ligand used is above the solubility of the solvent. The method involves evaporating off the solvent while sorbing the extractant to each porous support particle. Resin 3 like resin 1 should have worked based on the extraction method developed in chapter 7 assuming that the none of the 0.8 M TOA added to the resin was lost. Like the previous analysis of resin 1, it is likely that steric hindrance between ligands caused the lack of Mn extraction.

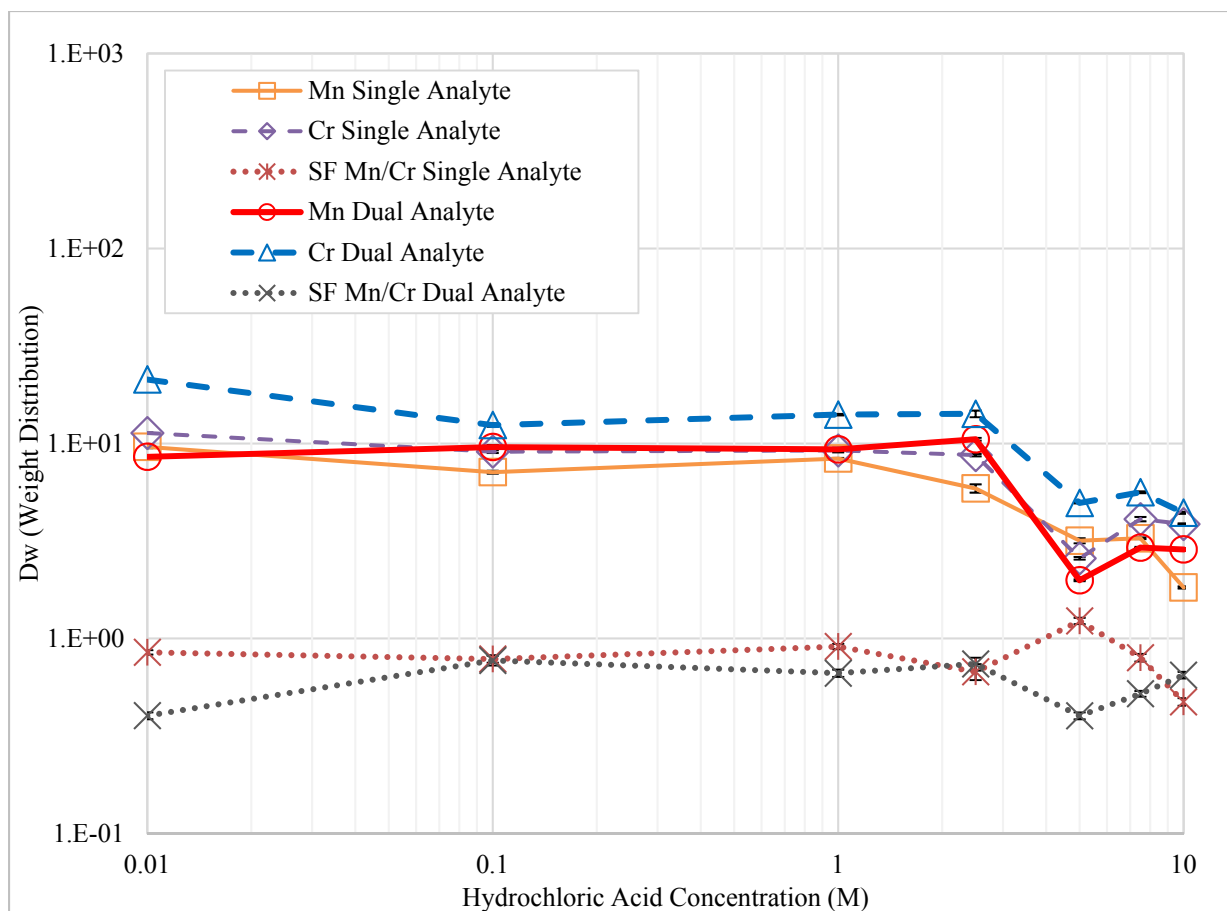

Figure 42: Single and dual analyte batch contact studies using resin 4 in hydrochloric acid

In figure 42, a higher weight distribution was seen for Mn and Cr in both studies with significant overlap over the acid range. At 0.01 M, retention by Cr and Mn was between ~8.5 and 21.3 representing a range in sorption equivalent to ~12 to 25%. All of the measured distribution ratios show a slight decrease to ~12 at 0.1 through 2.5 M. A decrease in weight distribution to ~3 is shown as the acid concentration from 2.5 to 10 M. The SF for single and dual analyte studies fluctuated at or slightly below 1 across the entire range.

Resin 4 produced for these studies was composed of 29 to 1 to 70% TOA to decanole to Amberchrom CG71. The higher distribution seen at low acid showing a decreasing trend is likely due to an increase in sorption to the inert support. Overall a higher distribution was shown across the range relative to previous studies using only 60% Amberchrom CG71. The loading for this resin of extracting ligand was decreased by 11% while the inert support was increased by 10% which could account for small but significant increase in retention seen. It is likely that this is the case as the retention was higher at low acids when oxide and hydroxide species would likely form and have been known to adhere the container. As the chloride concentration increased, the dominant species changed for Mn and Cr causing this decline. However, it is difficult to discern why Cr has a slightly larger retention than Mn across the entire the acid range. Use of decanole in this resin likely used as a slight diluent to help solvate the TOA ligand to promote sorption to the inert support in production.

Figure 43: Single and dual analyte batch contact studies using resin 5 in hydrochloric acid

In figure 43, a lower weight distribution relative to resin 4 but similar to resins 1, 2, and 3 is shown for Mn and Cr in both studies with significant overlap over the acid range. The weight distribution for both analytes was below  $\sim 5.7$  equivalent to a sorption of  $\sim 8\%$  while the separation factor fluctuated slight above 1 across the entire range.

Resin 5 produced for these studies was composed of 37.5 to 2.5 to 60% TOA to decanole to Amberchrom CG71. The return to a sorption less than 10% shows that the relative amount of support used may dictate the sorption mechanism for at least low acids concentrations. From 5 M

up to 10 M the weight distribution measured for both acids is similar to resins 1 through 4 and likely means that majority of the retention being seen in each resin may be due to other mechanism aside from ligand extraction. This is likely as in none of the resins does extraction of Mn increase as the chloride concentration increase which was shown to occur in chapter 7. Additionally, a slight increase from 1 to 2.5% of decanole in addition to a 8.5% increase in ligand loading showed less retention so it is likely that decanole was used for the purpose of improvement sorption of the TOA ligand to the inert Amberchrom support. Similar to each of the previous resin studies, it seems that either insufficient ligand was used to extract Mn from the hydrochloric acid matrix or excessive ligand was used to causing steric hindrance. Alternatively, steric hindrance issue could be causing lack of extraction for all these ligands due to excessively long carbon chains. The TOA ligands relies on three R groups containing 8 carbons. Reduction in the number of carbons may help promote extract by allowing less overlap and a larger volume in the stationary phase for Mn to be extracted.

## **8.5 Conclusion**

Overall, the weight distribution ratio of Mn and SF of Mn to Cr was not shown to occur for any of the resins produced through Triskem. A weight distribution of less than ~10% was shown for Mn and Cr in hydrochloric acid for resin 1, 2, 3, and 5. Resin 4 showed a higher distribution ratio up to 25% at low acid followed by a decrease as the chloride concentration increased. The SF of Mn to Cr was shown to fluctuate around 1 for each resin regardless of the acid concentration. Additionally, the nitric acid studies using resin 1 replicated the lack of extraction seen in the solvent extraction work for Mn and Cr.

There are a large number of issues that affect the lack of extraction being shown based on the materials and production method. With limited information given, only the composition of each resin could be compared to discern why little to retention was seen in all resins but 4. Many factors influence the extraction potential such as pore size, particle size, inert support type, concentration of ligand, and ability of solvent or diluent to sorb the ligand to the support. Between resin 1, 2, 3, and 5, variations in solvent, inert support, and ligand concentration were adjusted with little to no change in retention. The only resin with any retention was resin 4 which was likely due to increase in the inert support relative to extracting ligand concentration. The distribution of both analytes were retained ~20 at 0.01 M decreasing down to ~3 at 10 M which seems to show that an increase in chloride concentration inhibition retention to the resin. The likely mechanism is by occlusion or sorption to the inert support as it seems likely that the TOA ligand was sterically hindered preventing extraction of Mn as the chloride concentration increased and  $MnCl_2$  became the dominant species in solution. Further work needs to be performed by replicating these batch studies using only the Amberchrom CG71 in an attempt to quantify the loss of analyte based on the hydrochloric acid concentration. Further discussion with Triskem is necessary to discern more information regarding this extraction and these resins. In the future, additional extraction chromatography studies may be performed using DGA, Ln1, and or actinide resin from Eichrom Technologies shown previously to preferentially extract trivalent species. Although, extraction of trivalent Cr while eluting off divalent Mn would require larger quantities of resin for a column separation to be performed.

## **CHAPTER 9: CONCLUSIONS AND FUTURE WORK**

### **9.1 Introduction**

In this research, three separate projects were performed for nuclear forensic and medicinal application. The nuclear forensics research was divided into two projects. The purpose of the 1<sup>st</sup> project to increase post detonation forensic knowledge through cross section determination of nuclear reactions occurring from a nuclear detonation. This was performed through measurements of activation products followed by calculation of cross sections using literature available to the public. The purpose of the 2<sup>nd</sup> project was to develop separation methods using commercial available materials for use in separating activation products. Separation of these activation products important for use in doping artificial urban debris melt glass at higher specific activity for further experimental studies. The purpose of the 3<sup>rd</sup> project was to develop a separation method for separation long lived positron emitting radioisotopes. In partnership with Triskem International, commercially available resins were produced based on separation method. Characterization of these resins were performed to determine usability. A summation of the different projects performed, their outcomes, and future work are described below in sections 9.2, 9.3, and 9.4.

### **9.2 Flattop Irradiations**

In chapter 4, activity measurements were taken of fast neutron activated elements commonly found in the urban environment and used in nuclear device materials. Individual twenty-four hour measurements were taken using a HPGe well detector for each of the four runs using the Flattop benchmark critical assembly. Samples in the critical assembly were irradiated using a neutron spectra produced from highly enriched uranium surrounded by natural uranium to

simulate the effect of a nuclear detonation. Each target sample contained one of the elements Au, Co, Cr, Fe, Ir, Ni, Pb, Pt, Ti, or W in a metal foil or salt form. Different elements were irradiated in different runs with the only constant being Au foil which was placed at the center of the assembly in each run. Previously, Au-196 and Au-198 produced from Au foil have been used to measure fission fractions accurately.<sup>12</sup> Based on this idea, and the knowledge that the power level kept consistent between each run,<sup>64</sup> neutron flux values for Au-196 and Au-198 were determined through use of fission spectra average cross sections obtained from the JENDL-4.0 nuclear library. These flux values were used to calculate cross section values for each activation product based on each specific nuclear reaction. The calculated values were then compared to literature values in an attempt to validate assumptions made during calculations. Literature cross sections for each specific reaction were obtained through the JENDL-4.0 or ENDF nuclear data libraries.

In all four runs, the deviation between either calculated cross section and literature cross sections was less than two orders of magnitude. The uncertainty of each cross section determined was less than 5% as the uncertainty was based only on the deviation in the activity measurement taken of each foil solution. In three of the runs, calculated cross sections for Os-191 (produced from natural Ir or Pt) or Co-60 (produced from natural Co) was found deviate by at least three and up to six orders of magnitude relative to literature value. This was likely due to a sensitivity to thermal neutrons or an energy threshold that was not accounted for when using the fission spectra average cross section to determine flux values. The fission spectra average values determined were based on an ideal neutron spectra which was not likely seen in these runs due to attenuation or scattering of neutrons in the assembly. Comparing the ratio of Au-198 to Au-196 flux values showed a factor of ~5 to 30 variation when comparing runs. This was likely caused by the same deviation from ideal conditions seen previously when comparing calculated cross section. A

correction would need to be made as Au-198 has a three order of magnitude increase for thermal neutrons relative to the ideal fission spectra average while Au-196 has energy threshold of 8.1 MeV lowering the total production of Au-196 relative to Au-198. Deviations in the calculated cross sections could be improved if the actual neutron energy spectra was made available for each run.

### **9.3 Extraction of Scandium from Titanium**

In chapter 5, multiple batch contact studies were performed to measure the retention of Sc and Ti in hydrochloric and nitric acid at varying concentrations. The extraction chromatography resins Ln 1 and DGA normal resin produced from Eichrom Technologies were characterized to determine optimal conditions for separating Sc from Ti. Batch studies using Ln 1 resin demonstrated retention of both analytes in hydrochloric and nitric acid with an optimal separation factor of ~300. However, at low acid concentrations in hydrochloric and nitric acid, a sizable portion of Ti (30%) was still retained to the resin. Retention of Ti increased with acid concentration up to ~85% near concentrated nitric and hydrochloric acid. Batch contact studies using DGA normal resin showed strong retention of Sc at nitric and hydrochloric acid concentrations above 2 M while minimal retention of Ti occurred. Single and dual analyte studies were performed using ppm quantities of analyte on DGA resin demonstrating a larger separation factor of ~8000 up to 25,000. Based on these SFs, a separation method was developed for column chromatography where a mixed solution of Sc and Ti could be separated on DGA resin in 5 M nitric acid. At high nitric acid, Sc would adsorb strongly to the stationary phase while Ti eluted through the column. Conversion of the resin to 0.1 M hydrochloric acid would allow for Sc to be stripped and recovered. Subsequent studies were performed at Colorado State University and Los Alamos National Laboratory showing similar results.

In chapter 6, gravity column studies were performed using ppm quantities of each analyte to test the separation conditions determined from the batch contact studies determined in chapter 5. A solution containing a 1:1 ratio of Ti to Sc in 5 M nitric acid was loaded onto a column filled with wet slurry resin. An elution profile was produced through collection of sequential free column volumes (FCV) at a flow rate of 0.25 mL/min (1 FCV is equivalent to 0.5 mL). Fractions collected showed a clean distribution of Ti in the load plus wash phase (5 M nitric acid) while Sc was recovered in the strip phase (0.1 M hydrochloric acid). Decontamination factors of at least  $10^3$  were determined for each fraction with a recovery of at least 98.6% for each analyte. The gravity column study method was adapted to vacuum column studies for the purpose of increasing the flow rate while separating a higher mass loading of Ti and Sc at a ratio of 1:100 which mimicked the ratio produced in chapter 4. These studies were performed at higher flow rates of 1, 3, and 5 mL/min with an average Sc recovery of ~99% and Ti recovery of ~95%. In these studies, stable Sc and Ti were used so further work should be performed to separate  $^{46-48}\text{Sc}$  from activated Ti foil for the purpose of doping artificial melt glass at higher specific activity.

#### **9.4 Extraction of Manganese from Chromium**

In chapter 7, a separation method was developed using solvent extraction to test the distribution of Mn from a mixed aqueous solution containing Mn and Cr in varied concentrations of hydrochloric or nitric acid. Two sets of studies were performed using ppb quantities of Mn and Cr to determine the distribution ratios based on varied trioctylamine (TOA) ligand and acid concentrations. In the 1<sup>st</sup> set of studies sets of studies, the acid concentration was varied while the ligand concentration remained static. This was reversed for the second set of studies. An increasing trend in distribution ratio of Mn between the organic and aqueous phases as the TOA and hydrochloric acid concentration was increased. Alternatively, Cr showed distribution ratios

less than 5 in both acids at any ligand concentration. At optimal conditions of 0.8 M TOA, and 8 to 10 hydrochloric acid, a distribution ratio of ~6 for Mn and ~0.01 for Cr was shown which is equivalent to a separation factor of ~600. Using the distribution ratios and SF, ~85% of Mn and less than 5% of Cr was extracted at these conditions. Alternatively, less than 5% extraction was shown Mn in any concentration of ligand and nitric acid. Further work need to be performed to test if Mn could be extracted by replacing the hydrochloric aqueous phase with nitric acid.

Additional kinetic and third phase formation studies were performed based on the initial solvent extraction studies. Each kinetic study involved repeating previous solvent extraction studies at mixing times of 10, 30, and 60 minutes to compare the distribution and SF of both analytes. The distribution ratio for Mn and Cr was shown be consistent for most acid and ligand conditions. The main difference seen was in 0.8 M TOA and 10 M hydrochloric acid which showed an increase in SF from ~544 at 10 minutes to 590 at 60 minutes demonstrating a ~8% change. In the third phase formation studies, the same TOA/acid concentrations as the kinetic studies were used to determine third phase formation. All studies performed used a 1:1 ratio of organic to aqueous phase with a total volume of 15 mL. Additionally, reduction studies were performed by adding the diluent 1-octanol until the emulsion disperses and two phases reformed. Third phase formation was found to occur in TOA concentrations of 0.1 M or higher in either acid at any concentration. Reduction studies using octanol found that ~2% (v/v) was sufficient to remove third phase formation in all hydrochloric acid systems while ~3% (v/v) was sufficient for nitric acid. Further work should be performed to determine an upper limit for octanol addition, as it has been shown that excessive use of diluents such as octanol or tri butyl phosphate (TBP) for third phase reduction can decrease analyte extraction. Although the purpose of this work was to develop a method for producing commercially available resins, this solvent extraction method

would be suitable for separating  $^{52}\text{Mn}$  produced from  $^{\text{nat.}}^{52}\text{Cr}$ . Additional work is required to test the capacity of the extraction based on the ligand concentration followed by scale up to match the concentration of each isotope produced from irradiation.

In chapter 8, extraction chromatography resins were produced by Triskem International based on the separation method developed in chapter 7. Each of these resins were composed of ~30-40% TOA ligand in solvent on 60-70% inert support. Cyclohexane and toluene were tested as solvents while Amberchrom CG71 and polystyrene divinyl benzene were used as inert supports. These resins were characterized for the retention of Mn and Cr at varying acid concentrations. Batch contact studies were performed using ppb concentrations of Mn and Cr in an attempt to replicate separation factors seen in chapter 7. Single analyte and dual analyte studies were performed using a slight variation of the method used in chapter 5. In each of the studies performed, a weight distribution  $D_w$  of less than 20 was determined equivalent to a less than 25% sorption to the resin. In resins 1, 2, 3, and 5, the retention was consistently below 10% in each acid system at any concentration. Limited information was provided due to proprietary reasons for each resin characterized. Additional information regarding the physical properties of each resin in addition to the production method used is necessary to discern why the solvent extraction method did not transfer to extraction chromatography. Further reasoning is outline in chapter 8 for reasons each of the resins would not work in addition to discussion of the speciation in hydrochloric and nitric acid at varied concentrations. Further attempts may be performed using Actinide (Ac), DGA, and Ln 1 resin from Eichrom in nitric and hydrochloric acid to alternatively extract trivalent Cr from divalent Mn.

## APPENDIX A: FLATTOP CALCULATIONS

### A.1 Sample Calculation with Assumptions for Chapter 4

#### A.1.1 Activity Determination for $^{198}\text{Au}$

A sample calculation for  $^{198}\text{Au}$  in run 1 (March 3<sup>rd</sup>, 2014 irradiation) is shown below using equation 9 and 10. A description of each variable unit is listed below each equation.

$$A = \Phi n \sigma [1 - e^{(-\lambda t)}] \quad (9)^{63}$$

n = Target areal density (# of atoms/cm<sup>2</sup>)

$\sigma$  = Cross section (cm<sup>2</sup>/1 atom)

$\Phi$  = Flux (neutrons/seconds)

t = Time of irradiation (seconds)

A = Activity at time zero/end of irradiation (Bq)

$$A_f = A e^{(-\lambda t)} \quad (10)^{63}$$

A = Activity at time zero/end of irradiation (Bq)

$A_f$  = Activity of individual foil solution ( $\mu\text{Ci}$ )

t = Time since end of irradiation plus detector measurement time (seconds)

The activated Au foil solution was measured and processed using the Genie 2000 software method described in section 3.2.2.1. All chemical or nuclear data used to process each gamma spectra or in subsequent calculations was taken from the Lund/LBNL isotope library.<sup>73,85</sup>

A value of  $3.23\text{E-}01 \pm 7.01\text{E-}03$   $\mu\text{Ci}$ /total solution was measured for  $^{198}\text{Au}$ . The irradiation end time was given as March 3<sup>rd</sup>, 2014 at 14:34:45. The measurement start time was March 5<sup>th</sup>, 2014 at 15:43:45 while the actual time of measurement was 3989.8 seconds. The difference between the end of irradiation and start of measurement time equaled 176,940 seconds. The decay constant value of  $2.98\text{E-}06$  (1/s) was plugged into equation 10 shown below.

$$A_f = Ae^{(-\lambda t)} \quad (10)^{63}$$

To solve for  $A$  using equation 10:

$$A_f = 3.23\text{E-}01 \pm 7.01\text{E-}03 \mu\text{Ci}/5 \text{ mL vial solution}$$

$$t = 176,940 + 3989.8 = 180920.8 \text{ seconds}$$

$$\lambda = 2.98\text{E-}06 \text{ seconds}^{-1}$$

$$A = 5.54\text{E-}01 \mu\text{Ci}/5 \text{ mL vial solution}$$

Converting to Bq using  $1 \mu\text{Ci} = 3.70\text{E+}04 \text{ Bq}$

$$A = (5.54\text{E-}01 \mu\text{Ci} / 1 \mu\text{Ci}) * (3.70\text{E+}04 \text{ Bq}) = 2.05\text{E+}05 \text{ Bq}/5 \text{ mL vial solution}$$

For all calculations in this work it was assumed that 0.25 mL of foil solution was brought up to 5 mL using a unknown acid in each vial measured for every run.<sup>86</sup> For simplicity, the density of water (1 mL/gram) was used to convert the total activity to units of Bq per gram.

$$A = (2.05E+05 \text{ Bq} / 0.25 \text{ mL}) * (1 \text{ mL} / 1 \text{ gram}) * 4 = 1.58E+06 \text{ Bq/gram}$$

Error was propagated through based on mainly on the uncertainty of the activity as no error was provided for the end of irradiation time, and insignificant uncertainty occurred for the elapsed measurement time.

$$A \text{ or the activity at the end of irradiation (time zero)} = 1.58E+06 \pm 3.43E+04 \text{ Bq/gram}$$

### **A.1.2 Flux Determination for <sup>198</sup>Au**

Using equation 9, the flux was calculated with an explanation of how each parameter was determined below. The target areal density was determined using the mass value of Au foil irradiated<sup>64</sup> and the assumption that the geometry of the metal foil target was a cube. This assumption was made due to a lack of geometric data for each foil in any run.<sup>86</sup>

The total mass of the naturally abundant <sup>197</sup>Au foil was 305.90 mg with a assumed purity of 100% for ease of calculation and lack of knowledge. No uncertainty was provided for the mass of foil given. The standard atomic mass unit density of 196.97 (g/mole) and Avogadro's number was used to determine the total number of atoms. The surface area was determined using the density of <sup>197</sup>Au (19.32 g/cm<sup>3</sup>) based on the cube geometry stated previously.

To determine  $n$  or the target areal density (# of atoms/cm<sup>2</sup>):

The # of atoms of <sup>197</sup>Au =

$$(305.90 \text{ mg} / 1000 \text{ mg}) * (1 \text{ gram} / 196.97 \text{ grams}) * (1 \text{ mole} / 1 \text{ mole}) * (6.023\text{E}+23 \text{ atoms}) \\ = 9.35\text{E}20 \text{ atoms of } ^{197}\text{Au}$$

The surface area for the Au foil =

$$(305.90 \text{ mg} / 1000 \text{ mg}) * (1 \text{ gram} / 19.32 \text{ gram}) * (1 \text{ cm}^3) = 0.02 \text{ cm}^3 \\ (0.02 \text{ cm}^3)^{(2/3)} = 0.06 \text{ cm}^2$$

$$n \text{ or target areal density} = (9.35\text{E}20 \text{ atoms of } ^{197}\text{Au}) / (0.06 \text{ cm}^2) = 1.48\text{E}+22 \text{ atoms of } ^{197}\text{Au/cm}^2$$

The time of irradiation was assumed to be 2 hours or 7,200 seconds for run 1 based on previously information given stating that all runs occurred for 2 hours.<sup>64</sup> However, it should be noted that in other communications, a different length of time was provided for runs 2 and 3 at 4,836 and 6,720 seconds. Two hours was used for runs 1 and 4 while these specific times were used for runs 2 and 3. No uncertainty was used for the irradiation time value in any runs due to lack of information. The decay constant for <sup>198</sup>Au is 2.98E-06 seconds<sup>-1</sup> and the fission spectrum average cross section value of 7.71E-26 cm<sup>2</sup>/atom was obtained from JENDL-4.0<sup>74</sup> for the n(<sup>197</sup>Au, <sup>198</sup>Au)γ reaction.

To solve for the flux, the activity at time zero in Bq/gram must be converted to Bq using the mass of <sup>197</sup>Au used to produce <sup>198</sup>Au which is 305.90 mg.

$$A = (1.58\text{E}+06 \text{ Bq/gram}) * (1 \text{ gram} / 1000 \text{ mg}) * (305.90 \text{ mg } ^{197}\text{Au}) = 4.84\text{E}+05 \pm 1.05\text{E}4 \text{ Bq}$$

$$A = \Phi n \sigma [1 - e^{(-\lambda t)}] \quad (9)^{57}$$

To solve for  $\Phi$ :

$n$  = Target areal density (# of atoms/cm<sup>2</sup>) = 1.48E+22 atoms of <sup>197</sup>Au/cm<sup>2</sup>

$\sigma$  = Cross section (cm<sup>2</sup>/1 atom) = 7.71E-26 cm<sup>2</sup>/atom

$t$  = Time of irradiation (seconds) = 7,200 seconds

$A$  = Activity at time zero/end of irradiation (Bq) = 4.84E+05 ± 1.05E4 Bq

$\lambda$  = decay constant (1/s) = 2.98E-06 seconds<sup>-1</sup>

$\Phi$  = 2.00E+10 neutrons/second

## CURRICULUM VITAE

### Lucas Boron–Brenner

Current Address: 1301 Burton Court, Apt. 4, Fort Collins, CO 80521

Permanent Address: 4568 Brighton Drive, Las Vegas, NV 89121

[Boronbre@unlv.nevada.edu](mailto:Boronbre@unlv.nevada.edu) · (301) 704 – 9211

### Education

---

**University of Nevada Las Vegas**, Las Vegas, NV. Expected graduation May 2018  
Ph.D. Radiochemistry, GPA: 3.9

**University of Maryland College Park**, College Park, MD. December 2010  
B.S. Chemistry

### Research Experience

---

**Colorado State University**, Fort Collins, CO. August 2016 – Present

Visiting Scholar

Advisor: Dr. Ralf Sudowe

- Determined and applied methods for separating radionuclides for use in positron emission tomography (PET) from activated target materials using solvent extraction and extraction chromatography.
- Stable analytes were measured using inductively coupled plasma atomic emission spectroscopy (ICP-AES) and inductively coupled plasma mass spectrometry (ICP-MS), while radionuclides were measured using  $\gamma$  spectrometry.

**University of Nevada Las Vegas**, Las Vegas, NV. August 2012 – Present  
Graduate Researcher

Advisor: Dr. Ralf Sudowe

- Measured prompt fast neutron activated transition metals to determine n, p capture cross sections using a high purity germanium detector (HPGe). Developed and applied methods to separate radionuclides from activated targets using extraction chromatography. Batch contact and column studies were performed with stable analytes and were measured using ICP-AES and MS.
- Measured time dependent concentration and forms of degradation products from methanol and nitric acid solutions used for actinide separation. Degradation products were measured using conductivity and infrared spectroscopy (IR).

**Los Alamos National Laboratory**, Los Alamos, NM.

Summer 2016 and 2017

Research Fellow

Advisor: Dr. Evelyn Bond

- Developed and performed column studies using anion exchange resin in nitric acid and methanol to separate uranium, americium, curium and europium. Fractions containing  $\gamma$  emitting radionuclides were measured using  $\gamma$  spectrometry while  $\alpha$  emitting radionuclides were measured by gross  $\alpha$  scintillation counting and  $\alpha$  spectroscopy.

**Lawrence Livermore National Laboratory**, Livermore, CA.

Summer 2013

Research Fellow

Advisor: Dr. Kim Knight

- Performed characterization of post detonation melt glass by size and shape through measurement of uranium abundance and isotopic ratios using isotope dilution ICP-MS.
- Spherical melt glass was digested using strong mineral acids and was spiked with a tracer prior to separation by ion exchange chromatography. Uranium isotopic concentrations were analyzed as a function of melt glass size and shape to determine glass formation by environmental and nuclear device mixing.

**University of Maryland College Park**, College Park, MD.

December 2008 – August 2010

Undergraduate Researcher

Advisor: Dr. William McDonough

- Performed laser ablation and standard addition ICP-MS of samples from the earth's mantle to measure elemental abundance and isotopic ratios. Geological samples were digested using strong acids or prepared by polishing and mounting using epoxides.
- Data processing was performed using Lamtrace data reduction software.

## **Fellowships and Awards**

---

- Nuclear Regulatory Commission (NRC) Graduate Fellowship, University of Nevada, Las Vegas, 2016 – 2018.
- Seaborg Institute Research Fellowship, summer 2016 and 2017.
- 2<sup>nd</sup> place Oral Presentation at the Central Rocky Mountain Health Physics Meeting, 2017.
- 1<sup>st</sup> place Oral Presentation at the American Nuclear Society Student Conference, 2014
- Glenn T Seaborg Nuclear Forensics Fellowship, summer 2013.

## **Professional Activities and Memberships**

---

- Institute on Global Conflict and Cooperation, Public Policy and Nuclear Threats Boot Camp. University of California, San Diego, July 2014.
- Thermal Ionization Mass Spectrometry (TIMS) Workshop, Idaho Falls, Idaho, May 2013.
- Nuclear Science and Security Consortium, Nuclear Analytical Techniques Summer School University of California, Davis, summer 2012.
- President of A Chi Sigma Professional Chemistry Fraternity. University of Maryland, A Rho Chapter, 2009 – 2010.
- Member of the Alpha Chi Sigma Professional Chemistry Fraternity.
- Member of American Nuclear Society.

## **Skills and Areas of Knowledge**

---

- Handling radioactive material
- Radioanalytical chemistry & Radiochemistry
- Radiation detection methods
  - Alpha ( $\alpha$ ), beta ( $\beta$ ), gamma ( $\gamma$ ), and x-ray radiation detection instrumentation.
- Analytical chemistry detection methods
  - ICP-MS, ICP-AES, UV-Vis, IR, IC, HPLC
- Separation Techniques
  - Extraction chromatography, ion exchange chromatography, solvent extraction

## **Presentations**

---

- L. Boron-Brenner, and R. Sudowe. "Separation Of  $^{52}\text{Mn}$  From  $^{52}\text{Cr}$  For Use In Positron Emission Tomography" Oral Presentation at the Methods & Applications of Radioanalytical Chemistry Meeting, Kailua-Kona, HI, April 2018.
- L. Boron-Brenner, and R. Sudowe. "Separation Of  $^{52}\text{Mn}$  From  $^{52}\text{Cr}$  For Use In Positron Emission Tomography" Oral Presentation at the Health Physics Society Midyear Meeting, Denver, CO, February 2018.
- L. Boron-Brenner, R. Sudowe, and E. Bond. "Chromatographic Separation of Actinides, Lanthanides, and Transition Metals" Poster Presentation at the Los Alamos National Laboratory Student Symposium, Los Alamos, NM, August 2017.

- L. Boron-Brenner, and R. Sudowe. "Separation of Fast Neutron Activated Titanium for Post-Detonation Nuclear Forensics" Oral Presentation at the Central Rocky Mountain Health Physics Society Meeting, Fort Collins, CO, April 2017.
- L. Boron-Brenner, R. Sudowe, and E. Bond. "Separation of Fast Neutron Activated Titanium for Post-Detonation Nuclear Forensics" Poster Presentation at the Los Alamos National Laboratory Student Symposium, Los Alamos, NM, August 2016.
- L. Boron-Brenner, R. Sudowe, "Chromatic Separation of Fast Neutron Activated Titanium for Post-Detonation Nuclear Forensic Analysis" Oral Presentation at the American Chemistry Society National Meeting, San Francisco, CA, August 2014.
- L. Boron-Brenner, and R. Sudowe. "Chromatic Separation of Fast Neutron Activated Titanium for Post-Detonation Nuclear Forensic Analysis" Oral Presentation at the American Nuclear Society Student Meeting, State College, PA, April 2014.
- L. Boron-Brenner, G. Eppich, K. Knight, and R. Sudowe. "Uranium Isotopic Measurements of Fallout Spherules Using Isotope Dilution Mass Spectrometry" Poster presentation at the Lawrence Livermore National Laboratory Student Symposium, Livermore, CA, August 2013.
- L. Boron-Brenner, and R. Sudowe. "Study of Scandium and Titanium Adsorption on Eichrom's LN resin in Hydrochloric, Nitric, Sulfuric Acid Matrices" Poster presentation at the American Nuclear Society Student Meeting, Boston, MA, April 2013.
