ABSTRACT

Innovation plays a vital role in corporate issues since it brings potentially appreciable profits and shores up their statuses in certain fields, although it may also harness firms, especially smaller ones, with high survival risks. This concern brings forth our research topic: will participating in innovation activities diminish small firms' risk of exit from the market? Our paper concentrates on hi-tech start-ups and complements existing firm dynamic studies by adopting a comprehensive annual survey dataset from a considerable science park located in Beijing. Using an efficient discrete-time proportional hazards model, and thanks to extensive data available, we can take a deeper investigation into this topic. Our research complies with most of the previous studies that show that the benefit from innovativeness outweighs the cost and we solidify our conclusions by considering a few distinctive features existing in China's economy.

1. Introduction

Firm dynamics have long concerned economists. Whether in developed or developing countries, the exit and entry of firms to the market are an essential part of industrial development (Bond, Tybout, & Utar, 2015). Recent years have seen a burgeoning increase in the number of start-ups in China, leading to one of the world's largest pools of unlisted companies. These fledgeling companies, however, have fairly high rates of exit from the market. This brings to the following question: What are the factors that assist new businesses or lead to their exit from the market? There are numerous studies about how innovation influences the dynamics of companies, but few have discussed this topic in regard to start-ups. Innovativeness, on one side, is one of the most important factors to measure a start-up's potentiality. However, contrary to the assumption of the neoclassical model that states that firms exist and make decisions to maximize profits, start-ups bear more associated risks in engaging in research and development due to the limited resources compared with large companies. Hence, in this paper, we delve into whether deciding to innovate have impacts on the survival of start-ups and, if they do, are the impacts positive or negative.

We refer to a survey that includes a series of start-ups operating at a science park supported by the government located in northwest Beijing named Zhongguancun. Known as China's Silicon Valley, Zhongguancun is the earliest and largest Science & Technology Zone plan launched by the Chinese government, which collocates some of China's most advanced hi-tech companies. Because of the strong agglomeration effects existing among the starters, this science park represents the highest level of innovation amidst fledgeling companies, which leads to broad meaning in research. By using an extensive annual corporate survey dataset, we discuss the innovativeness through two indexes derived from the survey. The first one is the number of patent applications, which

reflects the efforts of firms to innovate. In addition, we employ another indicator standing for firms' strategies on innovation, measured by the proportion of sales of new products to total sales. When combining these two variables, we can explore to which extent innovativeness, assessed either by input or output of innovation activities, influences the risk of exit. The survey dataset provides uninterrupted descriptions of each firm as long as they operate at the science park. This feature helps us to control the possible heterogeneity problems.

Following previous studies on corporate survival, we adopt the complementary log-log model, put forward by [Prentice and Gloeckler \(1978\)](#) in order to fit our data structure and solve the heterogeneity problems. This model helps to solve two major concerns with the data: discrete survival times and right censoring. Furthermore, we also exploit other attributes shown in the survey as control variables to avert biased estimation due to heterogeneous corporate characteristics. These attributes are some of the most typical features distinguishing companies in China such as the ownership, industry, and exportation, among others. We find that innovativeness has a significant positive impact on lessening the risk of exit, measured either by the number of patents or the sales ratio of new products. This result leads to the conclusion that the benefits to innovate outweigh the negative impacts it brings to a start-up. In other words, though a start-up has to bear the risk of running out of money, in general, innovation activities are an efficient way to diminish the risk of exit. Additionally, we consider different ownership structures existing in China and find that state-owned enterprises (SOE), those who tend to obtain subsidies more easily from the government, benefit from these subsidies in the form of a reduction in hazard rate. Moreover, we attempt to find the mechanism behind this finding, showing that innovativeness mainly promotes total factor productivity and average productivity per labor unit hired for start-ups.

This paper complements existing studies in four aspects. The cornerstone of our paper is that it is the first one to use a specific Chinese start-up survey dataset to discuss firm dynamics. This naturally irones out one aspect of the concern on endogeneity since unlike large firms, start-ups have to make a trade-off between investing in production and innovation given the limited assets available. The comprehensive dataset also covers more characteristics of companies compared to other large scaled corporate surveys. Second, we employ an efficient hazard survival model favoring right censoring, and solve potential heterogeneity problems thanks to a broad selection of variables provided by the survey dataset. Furthermore, the source of a patent and the destination of its application are investigated, helping us to dig into the distinctiveness of a patent, further exploring the quality of the innovativeness and its impact. Moreover, we ponder the mechanism behind the finding and discuss how innovation improves the corporate performance of firms.

This paper is structured as below: the second part reviews previous studies regarding the relationship between innovation and the survival of companies. In the third part, we introduce our dataset. The fourth part evaluates existing models we have on the table about firm survival. In the fifth part, we give the findings. In the sixth part, we conduct a battery of robustness tests to solidify our test results. The last part concludes.

2. Literature review

The prevailing perspective is that innovation can enhance the chance for firms to survive, often attributed to the benefits brought by innovation activities. Innovation can reduce the costs of production ([Cohen & Klepper, 1996](#)) and strengthen firms' dynamic capabilities, including distinctive processes, asset positions, and evolution paths ([Teece, Pisano, & Shuen, 1997](#)). It can also help firms deal better with government's regulations ([Costantini & Mazzanti, 2012](#); [Zhuge, Freeman, & Higgins, 2019](#)) and improve their potential and realized absorptive capacities ([Zahra & George, 2002](#)). Thus, when the benefits brought by the research and development activities override the cost, better fiscal performance is expected and longer survive in the market is more likely. There are a large number of studies that substantiate this point. [Arrighetti and Vivarelli \(1999\)](#) use an Italian small-firm dataset and find that innovation is related to a superior postentry performance. [Calvo \(2006\)](#) concludes that innovation activity, either measured by process or product, is a strong positive factor in the firm's survival and its employment growth based on a sample of Spanish manufacturing firms. [Cefis and Marsili \(2005, 2006, 2012\)](#) conclude that a positive connection exists between innovation premiums and life expectancy shown by adopting observations of manufacturing firms in the Netherlands. By considering patent portfolios in a group of French firms, [Colombelli, Krafft, and Quattraro \(2013\)](#) show that innovation enhances the survival likelihood of firms. Results in [Helmers and Rogers \(2010\)](#) indicate that intellectual property activity, measured as patenting and trade-marking, is associated with a considerably lower probability of exit by using a British dataset. [Wagner and Cockburn \(2010\)](#) find that in Internet-related firms that made an initial public offering on the NASDAQ, patenting is positively associated with survival. [Esteve-Pérez and Mañez-Castillejo \(2008\)](#) test a number of hypotheses mainly drawn from the Resource-Based Theory of the Firm and establish that firms with more assets concentrating on research and development enjoy better survival prospects. [Fernandes and Paunov \(2015\)](#) use plant-product data for Chile and find that innovating plants have a lower exit hazard.

However, there are a few circumstances in which the risk of innovation activities could beat the benefits brought by the process. [Cader and Leatherman \(2011\)](#) found omitted observations or missing data in previous studies using US data, resulting in erroneous conclusions, and technology-intensive firms were more likely to fail within the first five years. [Hyytinen, Pajarinen, and Rouvinen \(2015\)](#) adopt an different view using ex-ante measures and, find that a startup's innovativeness is negatively associated with its subsequent survival in Finland. Another interesting finding is from [Buddelmeyer, Jensen, and Webster \(2009\)](#) that although radical innovation, captured by the stock of granted patents, enhances survival prospects, firms are more likely to fail after investing in radical innovation, as measured by submitted applications. These studies capture some flaws in precursors and found the different conclusions. In a word, most of the previous research suggests that there exists a positive relationship between innovation and the chance to survive. Nevertheless, considering the aspects brought forth by the later papers, attention should be paid to the data accuracy and heterogeneous problems.

Our dataset has two major specific characteristics. One is that it only includes hi-tech companies, and the other is that our research is based in China, where the government plays an essential role in the development of the science park, and handouts from the government cannot be ignored. Start-ups are usually more proactiveness and competitive aggressiveness (Lumpkin & Dess, 1996). Theoretically, Dahlqvist and Wiklund (2012) think that a new venture, which is based on a novel business idea, may eventually outperform its competitors in the same field. Starters are also more flexible toward rapid changes happen in the market (Klepper & Simons, 1997). Therefore, we may assume the same positive association shown in Rosenbusch, Brinckmann, and Bausch (2011) that the relationship between innovativeness and small business performance is stronger for younger firms and can be seen in our dataset. Another point of interest is China's subsidy policy. Government subsidies have a positive certification effect on the acquisition of bank loans (Li, Chen, Gao, & Xie, 2018; Zhang, Du, Zhuge, Tong, & Freeman, 2019). Additionally, the subsidies can even boost the innovation itself. According to Dang and Motohashi (2015), patent subsidy programs increase patent counts by more than 20%. Zhang, Li, Zhou, and Zhou (2014) illustrates that government subsidies, in the long and short-terms, have significant positive effects on the financial performance of energy manufacturing companies.

Due to the hypotheses mentioned above, the next step for us is to see what economic models economists have on the table for the firm survival research. In earlier studies, we could find some traditional methods are adopted, such as OLS (Calvo, 2006) and Log-logistic models (Mahmood, 2000). The Cox Model, which was first introduced by Cox (1972) is popular in firm survival research thanks to its convenient estimation of the effects of plant characteristics on survival using a proportional shifter of the baseline hazard function with no requirements on that function's shape (Agarwal & Audretsch, 2001; Chen, 2002; Disney, Haskel, & Heden, 2003; Girma, Görg, & Strobl, 2007). Another discrete time survival model often employed is the complementary log-log model (Agarwal, Sarkar, & Echambadi, 2002; Bayus & Agarwal, 2007; Musso & Schiavo, 2008).

3. Data description

We adopt a firm-level annual survey dataset, which includes comprehensive information on small and micro-enterprises. These companies are hi-tech start-ups partly subsidized by the government and located in Zhongguancun Science & Technology Zone. The dataset covers the period from 2007 to 2013, and the number of firms in the survey each year exceeds 9000.¹ The frequency and ratio of each year are presented in Table 1 below.

The firm sample in our dataset covers six main industries including service, software, and wholesale. In addition, this dataset allows us to get access to other information like the ownership structures of the firms, financial condition, human resource condition, import and export trade, new products, R&D, and patent applications.

3.1. The status of a firm and its spell duration

In our model, the hazard rate is used to measure firm dynamics. To determine the hazard rate of the firms, we have to define their status, which is a binary variable: survival or exit. There are a few reasons that lead a firm to exit: mergers, acquisitions, bankruptcy, and so forth. However, thanks to the characteristics of our samples, we can track the information of firms as long as they are still located in the science park. Thus, it is much easier to define the status of the companies and their spell durations, compared to most previous studies (e.g. Fontana and Nesta (2009); Ugur, Trushin, and Solomon (2016); Buddelmeyer, Jensen, and Webster (2006)). In this paper, we define the status of exit when a company stops reporting. We show the exit rate for each year in Table 1. The average exit rate in our sample is 12.46%, which is lower than the average exit rate in China, where for the state-owned and private firms, it is 15.8% and 13.8%, respectively, from 2007 to 2012 (Hsieh & Song, 2015).

3.2. The innovativeness of firms

The firms innovation abilities are the major concern in this study. Herein, we use two approaches to measure a firm's ability to innovate. First, we consider firms' new products, which are the outcome of a firm's innovation activities. Following Howell (2016), Wang, Li, and Furman (2017), and Zhang (2015), we calculate the fraction of sales of the new product to total sales to measure how the innovative output influences the survival of the start-ups. A new product is the one a firm reported in the survey which the firm produced in that survey year but not previously. This indicator reflects the market strategy of a firm. If the firm puts more efforts on innovation, it will produce and sell more new products, base on which we can explore whether the strategy to produce and sell more new products is favorable to firm survival. Additionally, we take patent application into account, so that we can measure the input of innovation activities' impacts on the chance of surviving. Here, we use the number of applications for patents from the survey as the

¹ The full name of the data set is the Annual Survey of Zhongguancun National Hi-tech Science Park Enterprises Database. This database and annual survey are operated by managed by the Management Committee Office of Zhongguancun, and the survey results are reported to the Ministry of Science and Technology of China every year, which are used for the policymaking and evaluations. All enterprises appear in the survey are located in the science park. Even though these firms are part of hi-tech start-ups in China, they stand for the highest innovativeness level, which has a broad meaning in research corporate innovation. In general, the quality of this survey data is higher than the China Industrial Enterprises Database. The China Industrial Enterprises Database cannot guarantee the quality of the data reported by the firms, and can only be spot-checked. However, the companies in the Zhongguancun survey database have the responsibility to report accurately because every firm needs to get an annual inspection before applying for policy support, including tax exemption, grant-in-aid. Reporting inaccurately will lead to the firm getting blacklisted and consequently losing the qualification to apply for policy support.

Table 1
Firm stay and exit statistical description.

Year	Stay sample	Exit sample	Total number	Exit rate (%)	Percent
2007	12,932	1399	13,303	9.76	17.52
2008	11,501	2013	13,513	14.90	17.79
2009	10,534	926	11,455	8.08	15.08
2010	9394	914	10,307	8.87	13.57
2011	8534	772	9306	8.30	12.25
2012	7387	1629	9016	18.07	11.87
2013	7110	1941	9051	21.45	11.92
Total	67,392	9594	75,951	12.46 (ave.)	100.00

indicator, and we follow [Dang and Motohashi \(2015\)](#) using the improved logarithm form to process the number.²

3.3. Other control variables

From our comprehensive survey data, we can draw a number of other variables to include into our analysis to avoid biased estimations. According to the findings of previous studies, we choose those factors that might influence firms' dynamic processes. For our main regressions, we first consider sales growth, which is calculated as the difference in sales between year t and year $t - 1$ divided by the total sales in year $t - 1$. Capital intensity is also taken into consideration, presented as fixed investment per capita for each company. Additionally, firm subsidies are a factor that cannot be ignored that affects the growth of a firm. Thus, we use the proportion of the subsidy accounting for the total asset as the index. Other variables include firm size and age, measured by the number of employees and the years since the first operation, respectively. In [Table 2](#), we present the statistical description of all variables and calculate the difference between the state-owned enterprises (SOE) and privately-owned enterprises (POE) group and the POE and foreign-owned enterprises (FOE) group, which are presented by *DIFF1* and *DIFF2*, respectively.

In our robustness tests, we introduce additional variables in order to solidify our analysis. We introduce a few other indicators relevant to innovativeness, including the proportion of hi-tech labors over total staff, the number of trademarks the company applied for, and the number of publications. Another benefit of our dataset is that we include the source information of every patent. We can distinguish whether the patent is developed by the company itself or acquired from domestic or foreign companies. The information on companies applying for patents outside of China is also provided. From the survey, we also consider the corporate performance of firms, comprised of the Return on Assets (ROA), Total Factor Productivity (TFP), and productivity per capita.

3.4. Kaplan-Meier survival analysis

From our statistical summary, a basic trend showing a higher survival rate for more innovative firms can be seen. The Kaplan-Meier estimation is a fundamental method in survival analysis ([Kaplan & Meier, 1958](#)). It has become a basic and important method of dealing with differing survival times, especially when the right censoring problem exists ([Rich et al., 2010](#)). Another necessity of using the Kaplan-Meier survival analysis is because the hazard models we use are in a linear form ([Lee, Um, Lee, Mun, & Cho, 2006](#)); thus, non-linear survival curves may lead to biased estimation. We portray the Kaplan-Meier curves for firms from 2007 to 2013 in [Fig. 1](#).

The survival curves above represent the survival probabilities of innovative and less innovative firms, measured by whether they have new products that sold (top) or patents (bottom) in six years. Results show that the survival probabilities of more innovative firms are always higher than less innovative firms for the firms in our time range. This provides the foundation for our analysis using hazard models.

4. Model specification

To identify the impacts of innovativeness, which consist of both the input and output effort in our study, we consider how factors including innovation abilities and other control variables influence the hazard rate for the survival of start-ups. To begin with, we have to take a few points into account, which may violate the assumptions of conventional models and require us to figure out proper methods to solve them. First, the probability to exit is conditional, which means survival rates fluctuate with time. Second is a typical problem that exists in survival research. Due to the limitation of observations, in the end year, we cannot track if the company continues to operate or exit, which leads to the uncertainty.

First, we extend the proportional hazards model to discrete time, defining the survivor function at time t_j as the probability the survival time T is at least t_j .

² in detail: $\log(\text{Applications of patents}) = \log(\text{number of applications in year } t + 1/3)$. Since many firms do not have any patents in some years (0 value), the log value is not well-defined. The value is based on [[Pakes & Griliches, 1980](#)], where they treat the whole problem as one of finding a point on the logarithmic scale for these patent numbers being 0, and this is accomplished by adding a dummy variable to the independent variables for observations. In their models, the rough value between 0.1 and 0.7 shows efficiency to solve this situation.

Table 2
Statistical summary of variables.

Variable	Mean	SOE	POE	DIFF1	FOE	DIFF2			
Exit	0.106	1	0	-1	0.072	0.107	-0.035***	0.133	-0.030***

Robust standard errors in parentheses. Significant at *10%, **5%, ***1% confidence levels. Indicator 1 is the exit firms, meanwhile 0 is then existing firms, and - 1 is the difference between them. DIFF1 is the difference between SOEs and POEs. DIFF2 is the difference between POEs and FOEs. Scientists & Tech ratio is the ratio of total scientists and tech employees. New product is the output of new products. New sale is the sales of new products (1000 yuan). Grant ratio is the ratio of successful applications; New sale ratio is the ratio of the sales of new products to the total sales; Patents is the number of patents; Valid patent is the ratio of valid patent number to the total number of patent application; Paper and Trademark are the numbers of papers and trademarks; K Intensity is the capital intensity.

$$S(t_j) = S_j = Pr(T \geq t_j) = \sum_{k=j}^{\infty} f_k \tag{1}$$

where T is a discrete random variable taking value t_j with probability:

$$f_j = f(t_j) = Pr(T = t_j) \tag{2}$$

Then, we construct the conditional probability of firms to exit λ_j at the hazard time t_j , the point in time at which the company survives.

$$\lambda(t_j) = \lambda_j = Pr\{T = t_j | T \geq t_j\} = \frac{f_j}{S_j} \tag{3}$$

We realize that the survival function at time t_j can be reconstructed as the hazard rate at all prior time points in time t_1, \dots, t_{j-1} :

$$S_j = (1 - \lambda_1)(1 - \lambda_2)\dots(1 - \lambda_{j-1}) \tag{4}$$

In a word, this equation implies that if a firm survives to t_j , it has to survive to t_1 , and given that the firm survives to t_1 , it can survive to t_2 , and so on, until the firm survives to t_{j-1} .

Then, we need to proceed with the model in terms of the conditional probability. The first one is based on a logit model, which was put forward by Cox (1972). The hazard rate of firm i is under the condition represented by a series of covariate values \mathbf{x}_i , giving us the hazard of a company at time j : $\lambda(t_j | \mathbf{x}_i)$.³ We set matrix \mathbf{x} as $(\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_n)'$. The conditional hazard rate satisfies the logit form as below:

$$\frac{\lambda(t_j | \mathbf{x})}{1 - \lambda(t_j | \mathbf{x})} = \frac{\lambda_0(t_j)}{1 - \lambda_0(t_j)} \exp(\mathbf{x}\beta) \tag{5}$$

Here $\lambda_0(t_j)$ is the baseline hazard at time t_j , which is a hypothetical situation where the characteristics vector \mathbf{x} is $\mathbf{0}$,⁴ changing only with the varying of time intervals. Additionally, $\exp(\mathbf{x}_i'\beta)$ is the relative risk relevant to the covariate values \mathbf{x}_i . Accordingly, we can rewrite as:

$$\text{logit}\lambda(t_j | \mathbf{x}) = \alpha_j + \mathbf{x}\beta \tag{6}$$

where α_j equals $\lambda_0(t_j)$ in the logit form of the baseline hazard as $\text{logit}\lambda_0(t_j)$. The Cox model treats time as a discrete factor by introducing one parameter α_j for each possible time of the exit of an observation at t_j . This model does not suit our dataset mainly

³ Formally, $\lambda(t_j | \mathbf{x}_i)$ stands for the hazard rate of an individual firm i , and can be rigorously presented as $\lambda_i(t_j | \mathbf{x}_i)$. $\lambda(t_j | \mathbf{x})$ is a vector of the hazard rates for all firms at time j . However, in order to make the equations more succinct and consistent with previous research works, we just follow the original notation in the Cox paper.

⁴ Formally, the function $\lambda_0(t_j)$ is not directly estimated in software, but it is possible to recover an estimate of the cumulative hazard and, from that, an estimate of the baseline survivor function $S_0(t)$.

Fig. 1. Kaplan-Meier survival curves.

because the companies need to be placed in an order based on their exit times, although it does not require survival time to be a continuous variable. As we mentioned previously, our dataset is based on annual surveys; hence, the survival times of companies are distributed into one-year intervals, so it is not probable for us to identify the accurate exit order. As a result, the estimation of the Cox model could be biased (Cox, 2018).

Another alternative extension of the proportional hazard model regarding discrete time observation is through the complementary log-log method. In this model, we start with the survival function, which can be written as:

$$S(t_j | \mathbf{x}) = S_0(t_j) \exp(x\beta) \tag{7}$$

Here, $S(t_j | \mathbf{x}_i)$ stands for the probability that a firm with covariate values \mathbf{x}_i survives to time t_j , while $S_0(t_j)$ is the baseline survival function. Since we already know that $S_j = (1 - \lambda_1)(1 - \lambda_2) \dots (1 - \lambda_{j-1})$, we can rewrite the function with a similar relationship for the complement of the hazard function:

$$1 - \lambda(t_j | \mathbf{x}) = [1 - \lambda_0(t_j)]^{\exp(\mathbf{x}\beta)} \quad (8)$$

From that, we adopt the complementary log-log method to transform the right-hand side to a linear function, giving a new function:

$$\log(-\log(1 - \lambda(t_j | \mathbf{x}))) = \alpha_j + \mathbf{x}\beta \quad (9)$$

where α_j equals $\log(-\log(1 - \lambda_0(t_j)))$ is the complementary log-log (cloglog) transformation of the baseline hazard. The cloglog model can be fitted to our discrete survival data by generating pseudo-observations as before and fitting a generalized linear model with a binomial error structure and complementary log-log link. However, only under non-informative censoring is there no difference between adopting the binomial likelihood and the discrete-time survival likelihood for the logit and complementary log-log links. Because right-censoring is one of our major considerations to improve accuracy, the best strategy for us here is to follow the cloglog model. Another vital reason why the cloglog link is better than the Cox (logit) is that in our dataset, time is discrete, but we only observe it in a grouped form. In particular, results based on the cloglog link would be more robust to the choice of categories.

After choosing an apposite extension method for discrete-time observations, in the next step, we use the Maximum Likelihood Estimation (MLE) to obtain the coefficients, from which we can get a glimpse of the impacts of innovativeness on the survival of firms quantitatively. Since the dependent variable we set here is dichotomous coded as 1/0 standing for firm exiting or not, we need to further convert it to the probability to exit. Cloglog model is related to the Gompertz distribution, unlike these other estimators, such as logit and probit analysis, in that the transformation is not symmetric. In the cloglog model, we define the probability function as

$$Pr(y_j | \mathbf{x}_i) = \begin{cases} 1 - \exp\{-\exp(\mathbf{x}_i'\beta)\} & \text{if } y_i = 0 \\ \exp\{-\exp(\mathbf{x}_i'\beta)\} & \text{otherwise} \end{cases} \quad (10)$$

where y_i is the status of the firm. $y_i = 0$ stands for firm surviving and $y_i = 1$ is for firm exiting from the market or right-censored. The log-likelihood function for complementary log-log is

$$\ln L = \sum_{i \in S} w_i \ln F(\mathbf{x}_i'\beta) + \sum_{i \notin S} w_i \{1 - \ln F(\mathbf{x}_i'\beta)\} \quad (11)$$

where S is the set of all observations i such that $y_i = 0$. $F(z) = 1 - \exp\{-\exp(z)\}$, and w_i denotes the optional weights, which is usually set as 1. Next, we can follow the normal procedure of the MLE to get the coefficients. Similarly, as a comparison, we have MLE likelihood function of the Cox model as

$$\ln L = \sum_{j=1}^D \left\{ \sum_{i \in D_j} \mathbf{x}_i'\beta - d_j \ln \left[\sum_{k \in R_j} \exp(\mathbf{x}_k'\beta) \right] \right\} \quad (12)$$

where j indexes the ordered failure times $t_{(j)}$, $j = 1, \dots, D$; D_j is the set of d_j observations that fail at $t_{(j)}$; d_j is the number of failures at $t_{(j)}$; and R_j is the set of observations k that are at risk at time $t_{(j)}$. This formula for $\ln L$ is for unweighted data and we can see the order of failure is required for estimation in order to improve the efficiency.

5. Empirical findings and analysis

5.1. Effects of innovation on firm survival

In Table 3, we present the results of our main regressions concerning the relationship between innovativeness and hazard rate, and the three different methods are explicated. First, we observed that in all three regressions, innovation, no matter if measured by product or patent application, does reduce the risk of exit. For the regression considering product innovation as the main variable, the cloglog model shows the maximum value of the log-likelihood. When the year and industry are controlled, the coefficient on product innovation is significantly negative. This means that the higher the ratio of new products accounting for total sales, the less risk a company has to bear. Thus, innovativeness does count toward the survival of a firm. Additionally, capital intensity, subsidies from the government, and firm size all play an essential role in firms' survival. The higher capital intensity means more active firms participate in investment (Liu & Buck, 2007). Like innovativeness, showing dichotomy in profitability, investment plays a positive part in reducing the risk of exit. Subsidies, contributing to firms' growth is intuitive since it is a direct capital injection. Another interesting finding is that the coefficients on firm age and its squared form do not show any significant level in our regressions. This leads to a conclusion that the length of years does affect hi-tech start-ups' subsistence. Since we adopt the maximum likelihood estimation, the criterion to measure the efficiency of a model is reflected in the value of the log-likelihood. Among the three survival models, the cloglog model exhibits the highest adaptability.

5.2. Impacts of the ownership structures of firms

Another important firm characteristic we look into is ownership. Due to the complicated market structure in China, different ownerships lead to large differences from operation to management. According to the question set in the survey, we classify the companies into three categories: state-owned, privately-owned and foreign-owned. From our main regressions, SOEs show advantages in survival. Thus, we assume ownership could also be a critical factor influencing the extent that innovativeness lessens the

Robust standard errors in parentheses. Significant at *10%, **5%, ***1% confidence levels. The specifications have a binary dependent variable that is equal to 1 in the year of exit for plants that exit and 0 otherwise. The table shows marginal effects. For dummy variables, the marginal effect is the change in the probability of exit associated with a change in the variable from 0 to 1, and for continuous variables, the marginal effect is the marginal change in the probability of exit associated with a change in the variable evaluated at the means of other variables. The regressors are defined in Table 2.

risk of exit. In our dataset, SOE makes up the smallest part of all observations while POE accounts for over 86% of all the firms. Our major thinking about how does the ownership matter is from the perspective of the access to subsidies from the government. SOEs in China tend to benefit more from the government subsidies (Eckaus, 2006). In Table 4, we construct interaction terms concerning ownership and subsidy, and ownership and size. What is noticeable in the regression results is that the coefficients of SOEs are much larger than the other two. This is reflected both in the term for the number of patents and new products. The results highlight two inferences: firstly, SOEs tend to obtain subsidies from the government easier than FOEs and POEs, which helps to finance innovation activities and survive longer in the market. Secondly, SOEs also benefit more from the increment of the sizes. A similar conclusion can be drawn that larger SOEs have an advantage in the market through stronger abilities to support innovation activities (Table 4).

5.3. Exportation and patent sources

Next, we discuss whether the characteristics of firms influence the impacts of the innovation activities, reducing the risk of exit. As shown in Table 5, three factors are considered here, including whether the firm is export-oriented, the source of the patents, and the locations of firms applying for the patents, based on which we construct corresponding interactors. First, for exports, we divide the firms into two groups: those with export activities and those without. Those firms with exportation may have to face external regulations and foreign competitors. For innovation measured by patents or new products, the two groups do not show significant levels in the export term. However, both of them show significance in their interaction terms. This indicates that export-oriented firms can gain benefits from innovation activities. Innovativeness plays an essential role in the survival of export-oriented firms.

When it comes to the source of patents, we distinguish between companies according to whether they purchase patents directly overseas. What is astonishing is that for those who purchase patents overseas, the coefficients on innovativeness are much larger. In other words, those passive companies face higher risks of being non-innovative. This also reflects that the patent quality in China is not satisfying enough.

At last, we look at where those start-ups apply for patents. Here, we divide the participants into two groups: those that only apply

for patents in Mainland China and others that apply overseas as well. A large gap is also obvious between these two groups. The group with overseas patent applications is more sensitive to innovativeness improvement. We explain this phenomenon by the higher requirements for patent applications overseas. A one-unit increase in innovation abilities in terms of patent numbers requires more effort in the group applying for patents overseas.

The regressors are defined in Table 2.

5.4. The mechanism

Since we have discussed to which extent innovativeness can pare down the risk of exit, it is necessary to explore the mechanism behind it. We consider three factors that might be triggered by the increment of innovation: Return on Assets (ROA), Total Factor Productivity (TFP), and Labor Productivity per Person employed (*Productivity*). We use two steps and adopt a System-GMM model to test if the mechanism is logical. Firstly, we test the connection between these three indicators and hazard rate. In addition to that, we consider the exportation of firms because of the causality between productivity and export of firms (Melitz, 2003). In Table 6 Panel A, we replace the innovativeness indicators with corporate performance and further introduce the interaction terms between the performance and exportation. The results indicate that higher ROA, TFP and labor productivity benefits to reducing the hazard rate of firm survival. Those exportation-oriented firms especially gain favor from the raise of ROA, TFP, and labor productivity.

The second step, as shown in Panel B, where the lagged form of each dependent variable is also taken into consideration, discuss how innovation activities can benefit those corporate performances. We present our regression results in Table 7 Panel B. Columns 1–3 examine how new products work, and columns 4–6 are about patents. For our two innovativeness proxies, innovation activities prompt all of the dependent variables, which are closely related with corporate operations. This leads to the conclusion that firms apply for more patents and adopt the strategy to develop more new products will benefit from these innovation activities, which in detail, is reflected in the three indexes we test. Better corporate performance is usually related to a lower exit rate.

Robust standard errors in parentheses. Significant at *10%, **5%, ***1% confidence levels. The specifications have a binary dependent variable that is equal to 1 in the year of exit for plants that exit and 0 otherwise. The table shows marginal effects. For dummy variables, the marginal effect is the change in the probability of exit associated with a change in the variable from 0 to 1, and for continuous variables, the marginal effect is the marginal change in the probability of exit associated with a change in the variable evaluated at the means of other variables. The regressors are defined in Table 2.

6. Robustness tests

In the preceding section, we mentioned a few concerns that might cause biased estimations. In this part, we propose a number of robustness tests to solidify our conclusions. This involves a series of firm's internal characteristics and external operational environments, which may exert influence on the firm's financial condition.

6.1. Alternative regression methods

In our previous analysis, we mentioned that through improving the survival function, we could obtain less biased estimations. If that is the case, then changing the model will not affect the significance level. Whereas the cloglog model is the uniquely appropriate one for grouped data from the continuous proportional hazards model, in practice, the model with a logit link (Cox) is used more frequently, because the logistic regression is better known, and software for this model is more widely available.

In Table 8, we adopt three different methods in lieu of the cloglog model to test the trend. Column 1 and 4 present the regression results from the Cox proportional hazard models. Column 2 and 5 explicate the results from general OLS models while considering firm-level fixed effects. And last, column 3 and 6 give the results from continuous-time parametric survival models, where the distribution of the hazard function is assumed as a Weibull distribution. We control the heterogeneity in the models by set firm-level random effects with the assumption that they are uncorrelated with other explanatory variables. From the results, even though fewer

The regressors are defined in Table 2. L. means the lag form, which stands for last-period value.

significant log-likelihood values could be observed, we still find a significantly negative correlation between innovativeness and hazard rate. Therefore, these tests indicate using other less accurate regression models can still capture the trend existing in start-ups.

6.2. Alternative innovativeness measurements

Patents are a conventional symbol reflecting the innovation ability of a firm. In this paper, we proposed our own method: the sales of new products which reflects firms' market strategy on the investment on new products. Here, we continue to make a more detailed exploration of the relationship between innovation and firms' dynamics. There are two major caveats in our analysis that come from adopting those two innovativeness proxies. First, can these two indicators accurately reflect the innovation abilities of firms? If we use other measurements, will the results change? Second, since both the patent application and sales of new products represent the outcome of investment in innovation activities, does the effort in research and development also have positive impacts on firm survival?

We use three groups of other indicators that stand for the efforts, outcome and the efficiency of the innovation activities of a firm. The first group includes R&D expenditures and the numbers of researchers and scientists. Apart from that, we consider heterogeneities among different industries. Since different industries have different innovation activity intensities, we also replace previous new product variable with the one divided by the industry average. This is the first step needed for firms to innovate and reflects their investment in research and development. The second group consists of the number of trademarks applying for and publications. The third group considers the efficiency of firms' innovation activities, which is reflected by the output of new products or patents per unit of R&D expenditure.

Table 9 shows the regression results of all five new indicators in which we use the cloglog models. The larger the coefficients of these five variables are, the higher the innovation abilities. We find the signs of coefficients of all new proxies in these two groups are significantly negative, which confirm our assumption again. This leads to a derivative conclusion that innovativeness, no matter in which form, could reduce the risk of exit for start-ups. More importantly, investment in innovation activities, no matter in what stage, could help firms to survive. Additionally, we found that not only the quantity matters but also the efficiency of these activities make a difference to the survival of firms. This answers the question in the background as well. Due to the limit of assets available, start-ups have to balance the investment between innovation activities and others such as marketing. In this case, the results tell that efficiency

The specifications have a binary dependent variable that is equal to 1 in the year of exit for plants that exit and 0 otherwise. The table shows marginal effects. For dummy variables, the marginal effect is the change in the probability of exit associated with a change in the variable from 0 to 1, and for continuous variables, the marginal effect is the marginal change in the probability of exit associated with a change in the variable evaluated at the means of other variables. The regressors are defined in Table 2.

is a key part so that starters cannot launch unfettered innovation activities.

6.3. The efficiency of firms' operations

In our previous regressions, notwithstanding, we controlled year and industry dummies in order to solve heterogeneity problems, but firm-level heterogeneity might still be a caveat to the accuracy of our regression results. Hence, we take a further step to consider the efficiency of firms' operations by considering the profitability of new products, success rate of patent applications, and risks facing the firms whole industry.

After taking these variables into account, we get new results shown in Table 10. Column 1 and 5 examine the proportions of sales of new products to total sales. We divide our observations into two groups: ones whose new products make up no less than 50% of total sales and the other with less than 50%. So here we can generate a dummy variable: *Less 50% Revenue* and *More 50% Revenue*, which is then timed with our former variables, either *Product Innovation* or *Patent Application*. The results show that the profitability does not influence the significance level. However, it is fairly noticeable that in a firm whose new products are less successful, innovation cuts down the risk of exit even more. This affirms that marginal effects on the impacts of innovativeness in terms of new product development exist. In other words, for start-ups, a one-unit input in innovation development is more rewarding in earlier stages. Another conclusion can be drawn from here, which is consistent with the previous test, is that firms cannot utterly rely on new products from innovation activities since we see more benefits if firms control the sales of new products below 50% of their total sales.

Another group of dummy variables are set up based on the percent of patent applications granted: *High Grant* means the rate is no less than 50%, and *Low Grant* stands for a rate lower than 50%. We use the same method to measure the effect of grant rate and innovation. The high grant rate group displays significant levels in the regression results. This finding points out that the quality of innovation outweighs the quantity. Only high-quality innovation, in terms of patents granted, can promote the survival of start-ups.

Robust standard errors in parentheses. Significant at *10%, **5%, ***1% confidence levels. The specifications have a binary dependent variable that is equal to 1 in the year of exit for plants that exit and 0 otherwise. The table shows marginal effects. For dummy variables, the marginal effect is the change in the probability of exit associated with a change in the variable from 0 to 1, and for continuous variables, the marginal effect is the marginal change in the probability of exit associated with a change in the variable evaluated at the means of other variables. The regressors are defined in Table 2.

Furthermore, another concern here is the risk itself. Samples in our survey cover many different industries, and different volatility levels exist in different industries. Hence, we introduce dummy variables representing the level of volatility in an industry: *High Vol* means the industry bears high volatility and vice versa. The results indicate that being in a high-risk or lower risk industry does not affect firm survival in the test of product innovation. However, innovativeness in less volatile industries is more effective at diminishing the risk of exit. This is reflected in both new products and patents.

7. Conclusions

Firms face uncertainties when innovating, which is particularly common in start-ups while huge profits could be foreseen due to the success of innovation or low efficiency of innovativeness leading to bankruptcy. In this paper, we test which situation exists in China through a comprehensive dataset consisting of hi-tech start-ups in a science park located in Beijing. We investigate whether innovation can reduce the risk to exit and if so, to which extent can innovation help the firm to avoid exiting. Measured by two indicators, the number of patents and the fraction of sales of new products, innovativeness in our paper is presented by efforts and

Robust standard errors in parentheses. Significant at *10%, **5%, ***1% confidence levels. The specifications have a binary dependent variable that is equal to 1 in the year of exit for plants that exit and 0 otherwise. The table shows marginal effects. For dummy variables, the marginal effect is the change in the probability of exit associated with a change in the variable from 0 to 1, and for continuous variables, the marginal effect is the marginal change in the probability of exit associated with a change in the variable evaluated at the means of other variables. The regressors are defined in Table 2.

outcomes. We adopt an efficient discrete-time proportional hazards model, the complementary log-log model, which helps us to solve the concerns about discrete survival times and right censoring. Assessed by both, our results show innovation diminishes the hazard rate for the firms to exit the market when other firm-level control variables are also taken into account. A 1% increase in the new product sale ratio or a gain of one patent application leads to a 0.147 and 0.151 unit reduction in hazard rate, respectively. A series of robustness tests were conducted to solidify our conclusions including adopting different survival models and indicators proxying innovativeness, testing the efficiency and quality of innovation, and incorporating firms' corporate characteristics and performance. Furthermore, we seek to uncover the mechanism behind the results in order to have a full understanding of how innovativeness operates in start-ups in which ROA, TFP, and productivity all play vital roles.

These findings raise a few policy implications for the government as well as for the start-ups. First, firms should be encouraged to innovate since both small and large firms benefit from new products and patent applications. Innovation favors firms at the micro level by reducing the risk of exit and at the macro level, to some extent, by helping industries upgrade. Second, the reducing effect is even more obvious in a more dynamic market. In our research, these start-ups that involve exports or acquiring activities get more reduction in the risk of exit from innovation. Thus, it is strategically reasonable for the government to make the market more open. Third, there is still a huge gap between state-owned and private companies benefiting from commercial activities, which is reflected here as the risk of exit. Hence, a fairer stage for competition should be made for both SOEs and POEs.
